Abstract

Development and validation of predictive methods for structural response of containment vessels in nuclear power plants to the overpressures that may be experienced during the unlikely occurrence of a severe accident continue to be of interest in the United States and the international community. As part of an international joint program sponsored by the Nuclear Power Engineering Corporation (NUPEC) of Japan and the U.S. Nuclear Regulatory Commission (NRC), Sandia National Laboratories (SNL) conducted a high pressure test of a steel containment vessel (SCV) model. The test model is nominally based on a Japanese Improved MK-II boiling water reactor containment. It is one-tenth in overall size but has wall thicknesses at one-fourth scale. In addition to the SCV model, the test includes an external contact structure (CS), a thick steel conical shell that covers most of the SCV with a nominal gap between the walls of the two structures. The nominal gap size was selected to allow the SCV model to deform as a stand-alone structure beyond the elastic range prior to its contact with the CS.

An objective of the test is to develop a set of validated methods that can be used to predict the response of containment buildings subjected to severe accident loads. Measures of structural response of the containment include displacement and strain during loading and characterization of the failure. Failure is characterized by the internal pressure at failure, the failure mechanism, and the location of failure. This test also allowed specific features of the SCV/CS interaction to be studied, including closure of gap, progression of contact, and load sharing.

This report describes finite element analyses conducted by Sandia in support of the overall design of the model and the development of the instrumentation plan, and for prediction of model behavior during the test. Preliminary scoping calculations were performed to answer design questions such as the effects of mixed scaling of the SCV model and the effects of including a contact structure in the test. These analyses were also used to answer modeling questions such as the best types of elements to use, the effects of friction between the SCV and the CS, and rational extrapolation of the materials tests for input to the finite element code. Global and local analyses were then conducted to examine the response of the final design using actual material test data. First the global response was predicted using both axisymmetric and three-dimensional shell models. Subsequent detailed local submodels were developed to refine features included in only a coarse fashion in the global analyses. These local analyses included an axisymmetric continuum analysis of the top head and a three-dimensional shell analysis of the equipment hatch region. Finally, one selected as-built feature, local wall thinning detected in the area of the equipment hatch, was incorporated into the local submodel of the equipment hatch.

Executive Summary

Development and validation of methods for predicting structural response of containment vessels in nuclear power plants to the overpressures that may be experienced during the unlikely occurrence of a severe accident continue to be of interest in the United States and the international community. As part of the Cooperative Containment Program sponsored by the Nuclear Power Engineering Corporation (NUPEC) of Japan and the U.S. Nuclear Regulatory Commission (NRC), Sandia National Laboratories (SNL) will conduct a high pressure test of a steel containment vessel (SCV) model. This report describes finite element analyses conducted by SNL in support of the overall design of the model and the test and for prediction of model behavior during the test.

The SCV model is nominally based on a Japanese Improved MK-II boiling water reactor containment. A mixed-scale design was used for the SCV model. The overall geometry of the model was scaled at one-tenth to facilitate shipping of the model from Japan to the United States, but the shell thicknesses were scaled at one-fourth for manufacturability and material availability. The top head, knuckle region, and stiffeners were also scaled using this mixed-scale approach and were not designed to simulate buckling or bending behavior of the actual containment vessel. The SCV model includes an equipment hatch penetration with the reinforcement plate, the drywell head, and a material interface in the vessel wall where two different steels are welded together. The equipment hatch sleeve and the top head flanges are not to scale. The equipment hatch cover is welded shut, and the top head flanges are represented as a single thick ring rather than separate flanges bolted together. All other hatches, airlocks, and penetrations have been omitted from the model. In addition, the lower wetwell and wall-basemat junction have been replaced with a thick bottom head designed to remain essentially elastic throughout the test. Finally, all internal structures not integral to the vessel wall have been omitted. Detailed drawings of the SCV are included in Appendix A.

In typical Japanese Improved MK-II plants, the steel containment vessel is inside a reinforced concrete shield building. Axisymmetric finite element analyses of the actual containment inside an idealized rigid shield showed that the response of shielded and

unshielded containments would be quite different. Notably, the analyses showed that the location of the highest strains in the high pressure regimes shifts from the middle conical sections of the unshielded containment to the top head region of the shielded containment. Therefore, the test has been designed to include a conical steel contact structure (CS) on the outside of the SCV model. While the CS in no way provides the same restraining effect on the SCV model as that of a reinforced concrete shield building on an actual containment vessel, it does force modeling of the contact and more closely represents an actual containment scenario than a test of an unshielded model. Appendix A includes drawings of the CS.

Preliminary finite element analyses were performed to evaluate the effects of the proposed mixed scaling on the model behavior and its relationship to the actual containment. While results showed that overall behavior was similar at the correctly scaled pressures, concern still exists over the effects on localized bending and the potential for top head buckling. In particular, since the critical pressure for buckling of the torispherical top head is approximately proportional to the ratio of wall thickness to radius, the mixed-scale SCV model (in which this ratio is 2.5 times that of the actual containment) is much less susceptible to this mode of failure. Therefore, the data from this test should be regarded as a validation of numerical modeling techniques that can then be applied for analysis of an actual containment, but the behavior of the actual containment cannot be directly inferred from the results of the test or the analyses of the mixed-scale model.

Finite element computations were also performed early in the program to answer numerical modeling questions such as the best type of elements, an appropriate value for the coefficient of friction between the SCV and the CS, and how to extend the provided material data to the range required for failure analyses. Axisymmetric analyses of the actual containment indicated that the two-node shell element represented the SCV wall quite well, except in the area of the top head where large thickness transitions occur. In this area, continuum elements are probably necessary for good local results. Axisymmetric shell analyses of the SCV model with a preliminary conceptual design of the CS indicated that

the two-node sliding interface element could be used to model contact between the structures and that model behavior was not significantly affected by coefficients of friction ranging from 0.1 to 0.5. In the final series of preliminary analyses, uniaxial test data provided by Hitachi were extrapolated beyond the point of maximum load in the tensile test using an axisymmetric continuum model of the test specimen.

The analyses used for pretest predictions of the behavior of the SCV/CS model were based on design information available at the time of the analyses and uniaxial test data of the actual material used to construct the model. Except for one analysis of the area around the equipment hatch, as-built geometric information was not used.

Global axisymmetric shell analyses were used to predict overall containment behavior. Two-node shell elements were used for the SCV wall and four-node continuum elements for the contact structure. Contact between the two structures was simulated using two-node interface elements that can accommodate large sliding. The coefficient of friction was assumed to be 0.20. These analyses indicated that the highest strain occurred in the top head.

A three-dimensional shell model of one-half of the structure was developed to incorporate the equipment hatch and reinforcement plate, the only non-axisymmetric feature in the model. Four-node shell elements were used in the vessel wall, along with four-node interface elements for the contact. However, in the three-dimensional analysis, the available contact simulation algorithm was limited to small relative sliding between the structures. As in the axisymmetric shell analyses, the coefficient of friction was assumed to be 0.20. This global three-dimensional model indicated locally high strains in the area around the equipment hatch insert plate near the material interface.

Output from the global three-dimensional model was then used to develop three different localized submodels, (1) an axisymmetric submodel of the top head using continuum elements due to the thickness variations near the knuckle and flange, (2) a three-dimensional shell submodel of the equipment hatch area based on design thicknesses, and (3) a three-dimensional shell submodel of the equipment hatch area incorporating an approximation of wall thinning discovered during examination of the actual SCV model.

Results of the global axisymmetric and three-dimensional analyses based on the final design indicate that the two regions with the highest strain are the top head and the area near the thickened insert plate at the equipment hatch. Based on the final design of the SCV model, failure is equally likely to occur in either of these areas. However, the actual SCV model includes a region of unknown extent near the equipment hatch insert plate where the material is thinner than specified in the design. Results of the local finite element analysis that included an approximation of wall thinning in this area indicate higher strains near the equipment hatch than in the top head. The computed plastic strain in the thinned region of the SPV490 steel near the equipment hatch insert plate and the material interface reaches a level that suggests local ductile failure at an internal pressure of 4.5 MPa. Therefore, based on the inclusion of this as-built feature, failure is considered to be more likely to occur near the equipment hatch than in the top head.

The pretest analysis efforts have demonstrated that the analysis results for failure prediction are very much dependent on the local details that have been included in the analysis model. Because several of the known as-built features of the SCV/CS assembly have not been included in the pretest analyses, the analysis results will best serve to provide predictions of the global deformation of the SCV model and will be less reliable for local failure predictions.

Acknowledgments

This pretest analyses project was sponsored by the U.S. Nuclear Regulatory Commission (NRC). Special thanks are due to Dr. James F. Costello of the NRC for his guidance throughout the program.

The SCV model test program is jointly sponsored by the Nuclear Power Engineering Corporation (NUPEC) of Japan and the U.S. NRC. We are indebted to Dr. Hideo Ogasawara and Mr. Tomoyuki Matsumoto for their support and guidance. We are also grateful to Mr. Kuniaki Komine and other members of NUPEC and Hitachi for many discussions regarding analysis methods and results.

The authors wish to acknowledge the work of Dr. Billy J. Thorne in performing many of the early analyses. Thanks are also due to members of the International Nuclear Safety Department at Sandia, specifically to Dr. Vincent Luk, the SCV Test Leader, and to Mr. Michael Hessheimer, the NRC/NUPEC Project Leader. Others whose assistance is greatly appreciated include Dr. Brad Parks, who was the program manager for the first four years, and Dr. Robert Watson who served as the SCV lead engineer for the first three years of the program.

1. Introduction

1.1 Program Background

The performance of containment systems in postulated severe accidents is a matter of continuing interest and concern in both the United States and the international community. Testing and analysis of numerous scale models of containment buildings that are pressurized to failure have been conducted for several years at Sandia National Laboratories (SNL) as part of the Containment Integrity Programs sponsored by the U.S. Nuclear Regulatory Commission (NRC). The overall objective of the programs has been to develop test-validated methods that can be used to predict the performance of light water reactor (LWR) containment buildings subject to loads beyond the design basis.

Previous test programs sponsored by the NRC and carried out at SNL focussed on scale models of steel containment geometries typical of pressurized water reactor (PWR) and boiling water reactor (BWR) Mark III containment designs. SNL's pretest analyses results are also included in a Round Robin analysis activity (Luk and Klamerus, 1996) that provided a forum for various international analysis groups to share pretest predictions of the steel containment vessel (SCV) model behavior. However, BWR Mark I and Mark II containment designs have geometries distinctly different from PWR and BWR Mark III containments. The most significant structural difference is the region of sharp curvature in the top head of the BWR Mark I and II reactor containments. Currently, no experimental data exist for the validation of finite element modeling techniques for these types of containments.

SNL is now involved in a Cooperative Containment Integrity Program under the joint sponsorship of the NUPEC of Tokyo, Japan and the NRC. This program grew out of the realization that there was sufficient similarity in goals in containment integrity research to warrant a cooperative effort between the United States and Japan. The focus of this new program remains LWR containments, but the current test is of a scale model of an SCV that represents some features of an Improved Mark II BWR containment vessel in Japan.

1.2 Objectives

One objective of the SCV test is to evaluate the validity of current methods for prediction of the performance of containment buildings subjected to severe accident loads and to identify areas needing improvement. Important measures of containment performance include the strain response during the loading history, the pressure capacity, the failure mechanism, and the location of failure. The test includes a thick steel shell contact structure (CS) that sits over the SCV model with a nominally uniform gap between the walls of the two structures. The nominal gap size was selected to allow the SCV model to experience deformation well beyond the elastic range prior to its contact with the CS. This test allowed specific features of the SCV/CS interaction to be studied including closure of gap, progression of contact, and load sharing between the SCV and the CS.

The pretest finite element analyses can be categorized based on their objectives. Early scoping calculations were performed to support the design efforts, mainly to answer questions regarding the effects of the mixed scaling of the SCV model and the effects of including the CS in the test. These analyses also answered modeling questions such as the best types of elements to use and the effects of friction between the SCV and the CS. Because these analyses were conducted before the material test data were available, nominal material properties were used. When uniaxial test data became available, finite element analyses of the test specimens were used to extrapolate the data for later input to the finite element analyses used for pretest predictions of the SCV model behavior.

Global and local analyses based on the final design geometry and actual material properties were conducted to examine the response the SCV/CS assembly. Except for one local analysis of the area around the equipment hatch, as-built geometric information was not used. The finite element models used for pretest predictions of SCV/CS behavior are described below and summarized in Table 1-1. All analyses of the SCV model were performed using current versions of the ABAQUS general purpose finite element code (ABAQUS, 1993a; 1993b; 1994; 1995).

Table 1-1. Summary of Pretest Prediction Analyses

Model	Purpose	Analysis/Type Elements
GAX18	Global behavior	Axisymmetric/1500 shell and continuum elements
GAX34	Global behavior with worst case gap dimension of 34 mm	Axisymmetric/1500 shell and continuum elements
G3DS	Global behavior with equipment hatch	3-dimensional/4800 shell elements
LTHAXC	Local behavior at top head and knuckle; include latest contact structure design	Axisymmetric/7200 continuum elements
LEHS	Local behavior near equipment hatch insert plate and material change interface	3-dimensional/4800 shell elements
LEHSTh	Effect of thinned area near equipment hatch insert plate and material change interface	3-dimensional/4800 shell elements

Global response throughout the loading history was predicted using both axisymmetric and three-dimensional shell models. Two axisymmetric shell analyses were performed to predict overall SCV model/CS response given two different sizes for the gap between the exterior surface of the SCV model and the interior surface of the CS. Both of these models incorporated the extrapolated uniaxial test data of the materials used in construction of the SCV model. However, properties of the CS were based on design properties for A36 steel because the CS design was in a preliminary phase at the time of the analyses. The first axisymmetric analysis (designated GAX18) included an 18 mm gap, the nominal gap size used for design of the CS. Because a worst case scenario based on fabrication tolerancing information postulated that the gap could be as much as 34 mm, a second axisymmetric analysis using a 34 mm gap (GAX34) was used as a bounding calculation. Results for stress and strain distribution histories from both axisymmetric models were evaluated and used to guide development of the mesh for the subsequent three-dimensional shell model.

Much of the SCV/CS assembly behaves as an axisymmetric structure. However, the design does include one non-axisymmetric feature—the equipment hatch with its surrounding reinforcement plate. Therefore, a global three-dimensional shell model (G3DS) based on the final design dimensions of the SCV model and the CS was developed to determine the effects of this non-axisymmetric feature. Like the

axisymmetric models, the three-dimensional shell model used the uniaxial test data for the SCV model and A36 steel for the CS. The only difference between this model and the axisymmetric model with the 18 mm gap is the explicit inclusion of the equipment hatch and reinforcement plate. This model indicated that the two areas of highest strain were the top head and the area around the equipment hatch. Although the global model could provide acceptable results for most areas of the SCV model, mesh refinement was required in areas of high strain gradients, especially in order to model response at internal pressures near failure. Therefore, two submodels with more refined meshes were developed for local analyses of the critical areas identified by the global analyses, the top head and the area near the equipment hatch.

The first local submodel was an axisymmetric model of the top head (LTAXC). This model was developed with continuum elements rather than shell elements to capture the stress and strain concentrations at the drastic changes in wall thickness near the knuckle and the top head flange. Boundary conditions from the global three-dimensional shell analysis were averaged over the circumference so they could be applied to the axisymmetric model. At the time this model was developed, the design of the CS had changed in the area near the top head. Therefore, the top head submodel used representations of the top head of the SCV model and the top of the CS that were both based on final design dimensions. However, the material of the CS was still assumed to be A36 steel.

The second local submodel based on final design dimensions was a three-dimensional shell model of the area near the equipment hatch and thickened reinforcement plate (LEHS). In this case, boundary conditions on the edge of the local mesh were applied directly from the global three-dimensional shell analysis. Stress and strain concentrations occur in this area due to a dramatic jump in thickness from the SCV wall to the reinforcement plate and because a material interface at which two dissimilar steels are welded together also lies in this region.

Finally, during on-site inspection of the SCV model, point measurements of the thickness of the SCV wall near the reinforcement plate indicated that the material had been thinned such that the as-built thickness was less than that specified in the design. Because this area had already been identified as one in which high strains occurred, a representation of the as-built wall thinning was incorporated into the local three-dimensional shell model of the equipment hatch (LEHSTh). Because the extent of the area over which the thinning occurs in the SCV model is not known, the thinning effect could only be approximated.

2. Test Article Description

The steel containment vessel (SCV) model, which incorporates some of the major features of a boiling water reactor (BWR) Mark II containment, was built in Japan by Hitachi Works, Ltd. and shipped to Sandia National Laboratories (SNL). At SNL, the model was enclosed in a contact structure (CS) made of carbon steel. The CS was designed to allow a minimum nominal gap of 18 mm between the exterior surface of the SCV model and the interior surface of the CS. The SCV/CS assembly will be tested within a fragment barrier designed to contain by-products of a catastrophic failure of the SCV. The fragment barrier is below grade and consists of a reinforced concrete floor and walls and a structural roof. Photos of the SCV model and the SCV/CS assembly on the test site at SNL are shown in Figure 2-1 and Figure 2-2.

2.1 Geometry

The geometries of the SCV model and the CS are described in detail in the following two subsections.

2.1.1 Steel Containment Vessel

The SCV model is scaled 1:4 in all wall thicknesses and 1:10 in overall geometry from a prototype Japanese BWR Improved Mark II containment. Whereas the design pressure of the prototype containment is 0.31 MPa (45 psig), the scaled design pressure for the mixed-scale SCV model is 0.78 MPa (113 psig).

Figure 2-3 shows an outline schematic of the SCV model with the CS. Detailed Hitachi drawings of the model are included in Appendix A. The SCV model consists of a number of sections with different wall thicknesses. Except at the knuckle, all thickness variations in the SCV model occur on its exterior surface so that the interior surface is smooth. Included in the SCV model is an equipment hatch opening with a thickened reinforcement plate. The hatch is not to scale, and the hatch cover is welded shut. In addition, the flanges of the top head (drywell head) are represented by a single thick steel ring scaled to match the hoop stiffness of the scaled flanges. The SCV model also includes several stiffeners and a material change interface where dissimilar steels are welded together with a full penetration weld. For convenience, the various sections of the model have been given

names (for example, the "spherical shell," the "lower conical shell," and the "knuckle") as shown in Figure 2-3. These names will be used throughout this report to refer to various locations on the model.

The portion of the SCV model above the ring support girder approximates the major features of an actual containment, but the lower portion of the model (i.e., the bottom head below the upper flange of the ring support girder, including the access hatch and other openings) does not. These parts of the model merely complete the pressure boundary. The SCV model was designed to ensure that neither leakage nor failure will occur below the upper flange of the ring support girder during testing, and that deformations in those areas will be negligible.

2.1.2 Contact Structure

Japanese Improved Mark II BWR containments consist of a steel containment vessel surrounded by a reinforced concrete shield building. (US containments are typically constructed of reinforced concrete with a steel liner.) Under severe accident loadings, it is anticipated that the steel containment vessel will grow until it contacts the surrounding shield building. The CS included as part of this test was intended only to allow investigation of the response of the SCV model against an almost rigid surrounding structure during pressurization, so that the behavior of the SCV was more representative of the expected behavior of actual plants. The CS was not designed to simulate the effects of the concrete shield building in physical plants.

The CS was designed to remain essentially elastic (i.e., only local yielding is permitted) until the SCV reaches an internal pressure of approximately 10 times its design pressure. Figure 2-3 shows the SCV/CS assembly. The CS was welded to the ring support girder with a partial penetration weld. Design drawings of the CS are also included in Appendix A.

The CS was designed to provide a minimum gap of 18 mm between the exterior surface of the SCV and the interior surface of the CS. This dimension was selected to ensure that at least one of the following criteria was met before contact occurred, despite reasonable variations due to fabrication difficulties and tolerances:

1. deformation in the conical section equals the scaled gap dimension (9 mm) between an actual BWR Mark II containment and its concrete shield building;
2. deformation in the knuckle region equals two times the scaled gap dimension;
3. strain measured by any functioning surface strain gage exceeds 5% (including the sum of membrane and bending strain and any strain concentrations).

The gap was also designed with the intent that generalized contact between the SCV and the CS would be made prior to structural failure of the SCV.

2.2 Materials

Materials used in the design of the SCV model and contact structure are described in the following two sections, respectively.

2.2.1 SCV Model

The portion of the model above the ring support girder is constructed of SGV480 steel and SPV490 steel. SGV480 steel is the material above the material change interface, and SPV490 steel is the lower material. Standard properties for these materials (Table 2-1) were supplied by Nuclear Power Engineering Corporation (NUPEC) of Japan. In addition, NUPEC provided results of standard uniaxial tests performed on specimens taken from the SCV material. These data are included in Appendix B.

The bottom surface of the ring support girder is spot welded to four steel support legs. These legs are bolted to the floor of the fragment barrier constructed to house the model.

2.2.2 Contact Structure

In the final design (Appendix A), the CS is constructed of 38 mm-thick, SA516 Grade 70 steel with a nominal yield strength of 258 MPa and an nominal ultimate strength of 476 MPa. The CS was fabricated by Chicago Bridge & Iron Services, Inc.

2.3 As-Built Features

Several measurements of the as-built SCV model and the CS were made. Measurements taken of the SCV before installation of the CS included thickness and radius of the SCV wall at several points around the circumference for various elevations. After the CS was installed, the gap between the exterior surface of the SCV model and the interior surface of the CS was also measured at several locations.

2.3.1 SCV Wall Thicknesses

Thickness measurements were made at Hitachi before shipment of the model to SNL. Details of these measurements are included in Appendix C. In general, the as-built SCV model is 5% to 10% thicker than the design. This would indicate that the actual hoop strains would be lower at a given pressure than those predicted by the finite element models based on design dimensions. However, near some of the weld lines, an occasional measurement indicates a thickness slightly (2% to 3%) less than the design. There is no way of knowing how localized this thinning is since there is a large distance between measurements.

Thickness measurements were also taken at SNL after installation of the model in the fragment barrier. Measurements made at SNL focused near weld seams where evidence of grinding was visible and near the equipment hatch. These measurements are also included in Appendix C. The measurements near the

Table 2-1. Nominal Material Properties

Property	SGV480	SPV490
Minimum yield strength	265 MPa	490 MPa
Tensile strength	480 to 590 MPa	610 to 735 MPa
Minimum elongation after fracture	17%	18% for 9 mm plate 25% for 17.5 mm plate

equipment hatch indicated an area of significantly thinned material, albeit of unknown extent. These data were used to study the effects of local wall thinning in a detailed finite element analysis of the area around the equipment hatch.

2.3.2 External Radii

On-site measurements of external dimensions of the SCV model were made by Chicago Bridge & Iron Services, Inc. prior to construction of the CS. The reported data shown in Appendix C give the radii measured from a calculated mean centerline at 45-degree increments around the circumference of the SCV at each of several elevations. These data indicate that, in nearly all the sections below the conical to spherical transition region, the radii vary less than 0.3% around the circumference. (Only one point in the lower conical section has a higher variation, which still is only 0.55%.)

2.3.3 Gap Dimensions

Appendix C also includes the results of measurements done by SNL on the gap between the exterior surface of the SCV model and the interior surface of the CS after installation. The only area in which the gap is less than the 18 mm design is near the top of the contact structure. Therefore, localized contact might initiate in this region somewhat earlier than predicted in the finite element analyses. However, this should not have a significant effect on the model behavior. Except near the equipment hatch, the gap varies from roughly 20 to 25 mm, which is greater than the 18 mm of the design but significantly less than the "worst case" scenario of 34 mm. This worst case scenario was investigated by finite element analyses prior to the contact structure design and is described in Section 5.3 of this report. The gap around the top of the equipment hatch is significantly larger at 27 to 33 mm but still below the 34 mm case investigated by axisymmetric analyses. Because all as-built gap dimensions fall within the bounds examined by the 18 mm and 34 mm axisymmetric analyses, additional analyses using specific as-built gap dimensions were not warranted.

3. Test Description

The steel containment vessel/contact structure (SCV/CS) assembly was subjected to monotonically increasing static internal pressure as described briefly in this section. Further details of the test sequence and the pressurization system are contained in the project test plan¹.

3.1 Pressure Supply

For the internal pressurization test of the SCV model, the pressure source consists of liquid nitrogen that is gasified and regulated to a constant pressure and temperature. The temperature of the nitrogen gas inside the SCV model is maintained to within $\pm 3^\circ\text{C}$ of the ambient temperature (15°C). This relatively constant gas temperature is achieved by setting the temperature at the pressure source location. Additional heating, if needed, is supplied by heaters before the nitrogen gas enters the model.

3.2 Pressurization Sequence

The pressurization sequence of the SCV test follows a monotonic rise of the internal pressure inside the SCV model until the model fails or the pressure level reaches $15.9 P_d$ (12.4 MPa, 1800 psig). The pressurization test will be terminated when the SCV model experiences a structural failure in terms of a catastrophic failure or a significantly large tear. If the SCV model leaks from the occurrence of multiple small cracks, then the pressurization system may not be able to maintain a constant pressure inside the model. At this time the SCV model will have experienced a functional failure, and the test will be terminated.

The internal pressurization test has three distinct stages in its test sequence:

1. first stage (0 - $4.6 P_d$)
2. second stage ($4.6 P_d$)
3. third stage ($4.6 P_d$ - model failure or $15.9 P_d$)

where P_d is the scaled design pressure (0.78 MPa). The entire test sequence is shown in Figure 3-1.

3.2.1 First Stage (0 - $4.6 P_d$)

According to preliminary analysis results^{2,3}, the conical section of the SCV model expands one scaled gap dimension of 9 mm at an internal pressure of approximately $4.6 P_d$, and the structure behaves essentially in the elastic domain throughout this stage. The end of the first stage of the test will occur when the average displacement of any array of four displacement transducers (0° , 90° , 180° , and 270°) at a given elevation is equal to 9 mm, regardless of the pressure.

3.2.2 Second Stage ($4.6 P_d$)

This pressure condition is held at a constant level for 30 minutes. During this stage, the SCV model behaves as a stand-alone structure; no contact occurs between the SCV model and the CS.

3.2.3 Third Stage ($4.6 P_d$ - model failure or $15.9 P_d$)

The SCV model behaves in the plastic domain throughout this stage. As the pressure continues to increase, the SCV model will take a longer time at each pressure step to arrive at a state of steady structural response. Accordingly, the incremental pressure rise for each step will be reduced, and the dwell time will be increased.

4. Finite Element Model Development

The finite element models described in this section were preliminary analyses used to develop confidence in the models eventually used for pretest predictions. Finite element analyses of the actual containment were used to select the element types. Early analyses of the steel containment vessel (SCV) model were used for a parametric study of the effects of including a contact structure (CS) in the test and the effects of friction between the two structures on SCV behavior. These early models of the SCV were based on nominal material properties for SGV480 and SPV490 steels obtained from published literature. Also described in this section are finite element models of uniaxial test specimens used to extrapolate the data obtained from uniaxial tests of the actual materials used in the SCV construction.

4.1 Selection of Element Types

Two-dimensional axisymmetric analyses are useful tools for capturing the global response of the SCV model and contact structure because the only non-axisymmetric feature is the equipment hatch. In addition, axisymmetric shell elements are convenient because their inherent coordinate systems have axes through the wall thickness and along the meridional direction of the shell. A question was raised about the accuracy of shell elements in areas of stress concentration due to the thickness variations in the SCV wall. An extensive study of the behavior of axisymmetric shell elements, compared to axisymmetric continuum elements, showed that the shell elements did indeed adequately model the transitions in wall thickness^{4,5,6,7,8}. However, additional axisymmetric continuum element analyses were indicated in the top head region at the knuckle and the flange where more drastic thickness variations

occur. The preliminary axisymmetric analyses also indicated that the two-node axisymmetric shell elements performed much better than the three-node elements, especially in the presence of contact, as long as the linear elements were sufficiently small to represent the curved surfaces in the model. Hence, all subsequent two-dimensional shell analyses were performed using two-node axisymmetric shell elements.

Global three-dimensional discretization of the SCV model and CS was required to get boundary conditions for local studies focused on the equipment hatch. Shell elements were the only feasible choice for these global three-dimensional analyses because the number of continuum elements required to sufficiently represent bending in the thin wall of the vessel would be extremely high. Four-node shell elements capable of representing finite membrane strains were used in these three-dimensional computations. For the local analysis around the equipment hatch, a fine mesh of these elements was used to ensure adequate representation of the geometry.

4.2 Friction Studies

This section documents early scoping studies regarding the behavior of the SCV model with an exterior CS. Both the influence of CS stiffness and of the amount of friction between the vessel and the CS were investigated. ABAQUS, Version 5.2 (1993a) was used for the computations described in this section.

4.2.1 Finite Element Model Description

All simulations described in this section were preliminary axisymmetric analyses of the SCV model with a conceptual representation of the CS that preceded the actual design (Porter, 1994)^{9,10}. The finite element model is shown in Figure 4-1. The finite element mesh for the SCV model consisted of 273 two-node axisymmetric shell elements for the shell walls, ring stiffeners, and top and bottom rings of the ring

support girder. Gusset plates used for stiffeners of the ring support girder, the top head flange, and the bottom head flange were modeled with 116 four-node axisymmetric quadrilaterals. The CS consisted of 86 two-node axisymmetric shell elements. The CS geometry in these analyses was based on an early conceptual design that completely enclosed the SCV model with gap dimensions based on one-tenth scale of the gap in the actual plant.

The symmetry boundary condition of no radial displacement was imposed on the two nodes which lie on the axis of symmetry of the model as depicted in Figure 4-1. The model was constrained in the vertical direction by fixing the vertical displacement at the node on the bottom outside corner of the ring support girder, so all vertical displacement results are relative to this point. This point was chosen because the SCV model is supported on legs attached to the underside of the ring support girder. The legs themselves were assumed to be rigid and thus were not included in the finite element model.

Gusset plates were welded between the upper and lower rings of the ring support girder to provide it with significant shear and bending resistance. To include the effect of the 32 gusset plates in the axisymmetric finite element model, we modeled them as a solid ring with an orthotropic material model and a reduced Young's modulus. The ring representing the gusset plates was assumed to have no stiffness in the hoop direction. The reduced stiffness in the axial and radial directions was obtained by multiplying Young's modulus of the actual material by the ratio of the actual area of the gusset plates to the area of the solid ring in the axisymmetric finite element analysis.

Note that the CS is attached to the top ring of the ring support girder at one node. Because both the top ring of the ring support girder and the CS are modeled with shell elements, this common point has only one rotational degree-of-freedom. In other words, the rotation of this node is constrained by both the CS and the ring, which is a realistic representation. Common shell nodes also enforce similar rotational constraints where the rings of the ring support girder and all internal ring stiffeners are attached to the SCV model.

Pressure was applied to the entire interior surface of the SCV model. The CS was only loaded through contact with the SCV model and its connection to the ring support girder. Contact between the two structures was

modeled with two-node, axisymmetric slide line elements superimposed on the SCV model shell elements. When contact occurs between the nodes of these elements and the elements on the CS, a stress is induced in the slide line elements in the direction of the normal. A tangential stress is also introduced if a non-zero coefficient of friction is specified.

The steel vessel was constructed of SPV490 and SGV480 steels. Because test data for the actual materials used in the model were not yet available at the time of these analyses, previously reported values from the published literature were used (Isozaki et al., 1986). The reported stress-strain behavior for these two materials was converted to true stress and true strain (Figure 4-2). The ends of the plotted curves represent behavior at the maximum load because conversion to true stress and strain is not possible beyond this point without knowing the reduction in cross-sectional area at the point of necking in the sample. The finite element code assumes perfect plasticity (no hardening) beyond the strains plotted in the figure.

In the first analysis, the CS was assumed to be nearly rigid by giving it a very high elastic stiffness and not allowing it to yield. Zero friction was assumed between the SCV wall and the CS. A second set of two analyses assumed the CS was constructed of SGV480 with the material response shown in Figure 4-2. In these analyses, the CS is referred to as "flexible" only to differentiate these analyses from the previous analysis with the "rigid" CS. For this set, both a frictionless model and a model assuming a coefficient of friction (μ) of 0.25 between the vessel wall and the CS were analyzed. Finally, in order to isolate the effects of friction on vessel behavior, a third set of simulations was run using the model with the rigid representation of the CS with coefficients of friction ranging from 0.01 to 0.5 by increments of 0.1.

The results discussed in this section of the report have been selected to demonstrate only the effects of CS rigidity and the effects of the amount of friction. More detailed results of model behavior based on later finite element models that more closely represent the final design SCV/CS are described in later sections.

4.2.2 Results

Figure 4-3 shows the finite element discretization of the top head and knuckle regions of the SCV model. The upper part of Figure 4-3 shows the part of the top head

where the cylindrical shell transitions to the spherical head. The first element above the top head flange is element number 156. The lower part of the figure shows the knuckle region. The knuckle itself consists of 10 elements numbered 130 to 139.

Results for the SCV response in the top head and knuckle regions are shown in Figure 4-4 through Figure 4-9. Figure 4-4 and Figure 4-5 show the history for the vertical displacement at the top of the SCV model. This displacement is caused by the strains in the top head itself as well as meridional membrane strains in the SCV wall from the top head flange down to the ring support girder, the point at which the vertical displacement is constrained. The latter meridional strains cause vertical rigid body motion of the top head above the flange. Figure 4-4 and Figure 4-5 show that the vertical displacement at the apex was the same for all simulations up to an internal pressure of 5.0 MPa. This is approximately the pressure at which full contact was achieved between the SCV model and the CS along the entire surface from the knuckle down to the top of the lower cylindrical shell. Above this pressure, the effects of friction and the rigidity of the CS on the top head displacement became more noticeable. Beyond an internal pressure of 11.0 MPa, the vertical displacement increased very rapidly due to extensive yielding near the center of the top head.

It is interesting to note that the displacement for the frictionless case was the lowest. In addition, all values of friction coefficient from 0.2 to 0.5 resulted in approximately the same vertical displacement, with 0.10 only slightly less. In all the analyses, the lower cylindrical shell yielded, leading to large radial expansion in this region which tends to pull down the containment wall above this section, thus decreasing the vertical displacement of the top head. However, if sufficient friction exists between the wall of the SCV model and the CS, this effect will be very localized near the lower cylindrical shell. Hence, the radial expansion in the lower cylindrical shell should have the greatest influence on the top head displacements in the case with the least amount of friction. Thus, the frictionless analysis should have the smallest vertical displacement at the apex as indicated in Figure 4-5.

Figure 4-6 and Figure 4-7 show the distribution of equivalent plastic membrane strain in the top head from the element just above the top head flange (element 156) to the element at the center of the top head (element 195) at an internal pressure of 6.0 MPa (for

clarity, every other element is represented by a symbol on the plots). Neither the stiffness of the CS nor the amount of friction appeared to influence the plastic strain in the top head. Therefore, the analyses results are identical. This similarity in strains indicates that the difference in vertical displacements at the apex of the top head after contact is established between the SCV model and the CS (as shown in the previous two figures) is due to differences in vertical rigid body motion of the top head flange caused by meridional strain below the flange; it is not due to differences in strain in the top head itself. It further indicates that the thick top head flange serves as a constraint against radial motion that is not affected by the presence of a CS.

Figure 4-8 and Figure 4-9 show the response in the knuckle region of the SCV model for various coefficients of friction. The knuckle region consists of elements 128 to 149, while the knuckle itself includes elements 130 to 139. Locations of element numbers indicated on the plots are depicted in Figure 4-3.

The effects of friction on the hoop strain are shown in Figure 4-8 and the effects on meridional strain in Figure 4-9, both for 6.0 MPa internal pressure. These results show that the only major difference was in the hoop strain. The hoop strain decreased as the coefficient of friction was increased. In particular, the results for the frictionless analysis showed significantly higher hoop strains than any of the analyses with non-zero friction in the knuckle region.

Figure 4-10 shows the finite element discretization in the upper and lower conical sections, as well as the location of the thickness changes and the material transition. Even though the equipment hatch could not be included in these axisymmetric analyses, its location is indicated because the global axisymmetric response is important in this region.

Figure 4-11 through Figure 4-16 show some selected analysis results in the upper and lower conical sections. The upper conical section contains elements 74 through 109, and the lower conical section consists of elements 34 to 73. For clarity, only every other element is represented by a symbol. Locations for all these elements are shown in the schematic in Figure 4-10.

The effects of friction on the hoop and meridional strain components in the upper conical section are shown in Figure 4-11 and Figure 4-12, respectively, at

an internal pressure of 6.0 MPa. The only notable difference shows in Figure 4-11, where the hoop strain for the frictionless case is higher than any of the cases that included non-zero friction. However, the value of the coefficient of friction between 0.1 and 0.5 appears to make little difference.

Results for the lower conical section are shown in Figure 4-13 and Figure 4-14. The effects of friction in this section of the model are basically the same as in the upper conical section. The major effect of friction appears in the hoop strain component, with the case of frictionless contact exhibiting a higher hoop strain than any of the non-zero friction analyses.

Figure 4-15 and Figure 4-16 show the vertical displacements at the elevation on the axisymmetric model corresponding to the top of the equipment hatch. The effects of friction were much more dramatic in this area. In fact, the presence of friction actually reversed the direction of the final vertical displacement at the top of the equipment hatch. This dramatic difference between a frictionless and a non-zero friction contact for internal pressures higher than 5.0 MPa was mainly due to deformations occurring in the lower cylindrical shell at these pressures. The lower cylindrical shell experienced large radial expansion at pressures beyond 5.0 MPa which, in the case of no friction, caused the vertical displacement of the equipment hatch to reverse direction and become negative when the pressure exceeded about 6.3 MPa. However, in the case of non-zero friction above a value of 0.2, the contact between the SCV model and the CS provided constraint against this tangential downward motion. In the presence of friction, the equipment hatch moved upward following the general conical shell deformation of the CS. Increasing the coefficient of friction above 0.2 had little effect on the vertical displacement at the elevation corresponding to the top of the equipment hatch.

Figure 4-17 shows the finite element discretization of the lower cylindrical shell area of the SCV model. The upper mesh shows the elements in the area where the SCV model transitions from the lower cylindrical shell to the lower conical wall section. The lower mesh shows the transition from the very thick spherical bottom head to the lower cylindrical shell. Element number 200 is the last element of the bottom head and element number 1 is the first element of the SCV model in lower cylindrical shell. Element 264 is the first

element of the CS where it attaches to the exterior ring support girder.

Figure 4-18 and Figure 4-19 show results for the response in the lower cylindrical shell of the model. As in the upper and lower conical regions, the effects of friction are visible only at an internal pressure higher than 5.0 MPa. The major effect occurs in the hoop strain component and is significantly different only for the case of a completely frictionless contact.

4.2.3 Effect of Friction on the Uplift Force

The amount of uplift that the CS imparts to the outer ring support girder can be estimated from the meridional stress in the CS at a point immediately above the support. Multiplying the meridional membrane stress by the cross-sectional area of the CS element just above the support girder (element 264 in Figure 4-17) gives the total uplift load. Figure 4-20 shows the uplift force for the two flexible structures (the force in the "rigid" structure is meaningless). Note that this is the total force exerted on the entire circumference of the ring. The results indicate that the effect of friction is to reduce the uplift force on the ring support girder.

4.2.4 Conclusions from Friction Analyses

Comparison of the results of these analyses demonstrated obvious differences between the models with no friction and those with some friction. However, the actual value of friction coefficient between 0.1 and 0.5 made little difference. Because the surfaces in the actual SCV model and CS are not lubricated, some friction can be assumed to be present. Therefore, all subsequent pretest prediction analyses described in Section 5, Section 6, and Section 7 were run using a coefficient of friction of 0.2.

4.3 Material Models

One of the most important components of any finite element analysis is the model of material behavior. The material model consists of two parts: the material data and the constitutive model. This section describes the methods used to ensure the best possible material modeling with the test data provided.

Material data in the form of results from tensile test specimens of the actual materials used in the SCV model construction were provided by Hitachi^{11,12} and are included in Appendix B. These data consist of measured load vs. elongation over a specified gage length up to the point of necking in the specimen. Over this range, load can be converted to engineering and true stress, and elongation can be converted to engineering and true strain by the use of simple analytical equations. However, the tensile tests represent only a simple unidirectional loading, while the SCV model is a complicated, three-dimensional object that will experience a multi-directional stress field under internal pressure and contact. Therefore, local true stresses experienced in the model may well be above those at maximum load of a tensile test specimen, and the data must be extrapolated by a rational method.

Furthermore, a constitutive model that best represents the entire range of extrapolated test data must be selected. Mild steels such as those that compose the SCV model are commonly represented by elastic-plastic materials with isotropic hardening. However, the form of the hardening curve is extremely important when attempting to model a structure far into the plastic region. In particular, the correct form for the hardening curve is essential for failure prediction (Wellman and Salzbrenner, 1992). It must be noted that these material models do not directly address failure. Failure must be treated in a post-processing step separate from the finite element analysis.

The true stress-true strain data from the uniaxial tests were used to fit a theoretical hardening curve such as a power law or inverse hyperbolic sine law¹³. In addition to capturing the measured behavior up to maximum load, prediction of the behavior of the SCV up to failure requires reasonable extrapolations of the true stress-true strain data beyond maximum load. The tensile tests were simulated using a finite element model to verify the behavior after maximum load. This section describes the procedure used to fit the material models to the tensile test data and to obtain reasonable extrapolations beyond maximum load.

4.3.1 Conversion of Test Data to True Stress and True Strain

In a tensile test, the engineering strain, e , is written in Equation 4.1:

$$e = \frac{l - l_0}{l_0} \quad (4.1)$$

where l_0 represents the initial gage length of the test specimen and l represents the current gage length of the test specimen. The engineering stress, s , is calculated directly from the load using Equation 4.2:

$$s = \frac{F}{A_0} \quad (4.2)$$

where F is the axial load on the tensile test specimen and A_0 is the original cross-sectional area. The true strain, ϵ , is defined as

$$\epsilon = \ln \frac{l}{l_0} \quad (4.3)$$

which is valid only for a homogeneous deformation over the gage length, and the true stress, σ , is defined as

$$\sigma = \frac{F}{A} \quad (4.4)$$

where A is the instantaneous cross-sectional area. By rearranging Equation 4.1 and combining with Equation 4.3, the true strain may be written in terms of the engineering strain:

$$\epsilon = \ln(l + e) \quad (4.5)$$

By using the constant volume relationship, $A_0 L_0 = AL$, and combining Equation 4.2 and Equation 4.4, the true stress may be written in terms of the engineering stress:

$$\sigma = s(l + e) \quad (4.6)$$

Equation 4.5 and Equation 4.6 assume that the volume is constant, the stress is uniform through the cross-section, and the deformation is homogeneous throughout the gage length. However, at the point of maximum load in the tensile test, the deformation localizes, necking occurs, and the assumption of homogeneous deformation throughout the gage length

¹¹ 14th Task Group Meeting Notes, CTG-14-04, November 16, 1994.

¹² Fax from Hitachi, December 20, 1994.

¹³ Carter, P.A., "Extrapolation of Hitachi Tensile Test Data," Sandia memorandum to V.K. Luk, June 6, 1995.

is violated. In addition, the stress distribution is no longer uniform through the cross-section. So, Equation 4.5 and Equation 4.6 are not valid beyond maximum load. Although the engineering stress decreases after necking because less load can be carried across the reduced cross-section, the true stress continues to increase (Dieter, 1986).

4.3.2 Procedure for Extrapolation of Test Data

The following procedure was used to obtain the necessary data. First, two different hardening plasticity models were fit to the experimental true stress-true strain data, which were available only up to maximum load, using a MATLAB (1992) curve fitting routine. These two models were chosen for their ability to accurately capture the hardening behavior of most steels. The first model is the power law hardening model shown in Equation 4.7 (Stone, 1997):

$$\sigma_e - \sigma_{ys} = A \left\langle \bar{\epsilon}^p - \epsilon_L \right\rangle^n \quad (4.7)$$

where A and n are the constants calculated from the curve fit, σ_e is the effective stress, σ_{ys} is the yield stress, $\bar{\epsilon}^p$ is the equivalent plastic strain, and ϵ_L is the Luder's strain or yield plateau. The use of the brackets, $\langle \rangle$, denotes the Heaviside function where the expression enclosed in the brackets takes the value of the enclosed expression when positive and otherwise is zero. The second model uses the inverse hyperbolic sine function and is shown in Equation 4.8:

$$\sigma_e - \sigma_{ys} = A \sinh^{-1} \left(B \left\langle \bar{\epsilon}^p - \epsilon_L \right\rangle \right) \quad (4.8)$$

where A and B are the constants calculated from the curve fit.

After determining which of the two hardening models provided the best fit to the data from each set of tensile tests, each set of tensile tests was simulated using the appropriate constitutive relation in the SANTOS finite element program (Stone, 1997). Figure 4-21 shows the axisymmetric finite element model used. Only the top half of the length of the round bar was modeled because it is symmetric about the plane normal to the axis of the specimen at the center of the gage length. To ensure that the localized deformation occurs at the center of the gage length, the diameter was reduced by 0.5–1.0%

at the plane of symmetry at the bottom boundary to provide an initial geometric imperfection. The specimen is restrained in the y -direction at the plane of symmetry, and displacements were imposed in the y -direction at the free end.

As shown in Equation 4.1, the engineering strain is obtained by dividing the change in the gage length or displacement by the original gage length. The load on the specimen can be converted to engineering stress by dividing by the original cross-sectional area as in Equation 4.2. The load-displacement data from the finite element analysis of the tensile test specimen were converted to engineering stress-strain data and compared to the engineering stress-strain data supplied by Hitachi in an attempt to verify the post-peak behavior. If the data from the finite element analysis did not correlate well with the Hitachi data, a new curve fit was tried and a new finite element analysis performed. This iterative process was repeated until reasonable post-peak behavior was obtained.

Hitachi performed a set of four tensile tests for each of the 11 different material/thickness combinations (two in the rolling direction and two in the transverse direction) for a total of 48 tests (one batch of tests was repeated). Table 4-1 summarizes the results of the curve fitting for the different SGV480 thicknesses; Table 4-2 summarizes the results of the curve fitting for the SPV490 thicknesses. For the SGV480 materials, the inverse hyperbolic sine law model worked best, while the power law worked best for the SPV490 materials.

Figures 4-22 through 4-32 consist of two plots each. The upper plot shows the true stress-true strain tensile test data sets along with the selected curve fit for each thickness of each material in the SCV model. The bottom plot in each figure shows the corresponding engineering stress-engineering strain data with the output of the finite element analysis of the tensile test. In other words, the top curves represent the fit of the constitutive model to the test data, and the bottom curves show the quality of the extrapolation of the test data beyond maximum load. The curves representing the finite element analyses using the theoretical constitutive models continue indefinitely because these models do not address failure. Failure must be assessed as a separate post-processing step after the finite element analysis of the SCV model is performed.

4.3.3 Implementation into ABAQUS

ABAQUS requires two options to specify an elastic-plastic material model: *ELASTIC, where the user specifies the elastic modulus and Poisson's ratio; and *PLASTIC, which specifies a metal plasticity model with a von Mises or Hill yield surface. For this option,

the user must specify the yield stress as a function of plastic strain, as a series of data pairs, each consisting of a true stress and corresponding log plastic strain value. The stress-strain curves generated by the material parameters given in Table 4-1 and Table 4-2 were converted to series of true stress-plastic strain data pairs for input into ABAQUS.

5. Global Axisymmetric Analyses

The analyses described in this section were used to provide guidance for the design of the contact structure (CS). Two axisymmetric finite element models were developed, one with an 18 mm gap and another with a 34 mm gap. These analyses also provided insight about the distribution of strain throughout the meridional distance along the steel containment vessel (SCV) wall in areas away from the location of the equipment hatch. Both models described in this section used the uniaxial test data with the extrapolations described in the previous section. Because the objective of these axisymmetric analyses was primarily to support the CS design (and not for prediction of failure), they were terminated at 8 MPa internal pressure or roughly $10 P_d$.

5.1 Finite Element Model Description

The basic finite element model of the SCV and CS for the axisymmetric analyses appears in Figure 5-1¹⁴. To support the CS design effort, two different gap dimensions, 18 mm and 34 mm, were examined. The CS was designed with a nominal gap of 18 mm, but fabrication tolerances could have resulted in gaps of 34 mm in some areas. The uniform 34 mm gap in the axisymmetric analysis provided a bound on the worst case.

Two-node axisymmetric shell elements were used for the SCV walls, ring stiffeners, and rings of the support girder. Four-node axisymmetric quadrilaterals were used for the flanges, gusset plates, and the CS. Two-node axisymmetric contact elements were superimposed on the shell elements at the midsurface of the wall of the SCV to model the contact between the SCV and the CS. The total number of elements used was approximately 1600 for both the 18 mm case and the 34 mm case. Based on the earlier parametric studies described in Section 4.2.1, the coefficient of friction used for these analyses was $\mu=0.2$ ¹⁵, so that when contact occurs, a tangential stress is induced in the contact elements in addition to a normal stress. Axisymmetric boundary conditions were imposed on

the node at the top of the hemispherical dome of the SCV as well as at the bottom hatch cover. The model was also constrained in the vertical direction at the bottom outside corner of the ring support girder. The loading consisted of pressure on the interior of the SCV and self-weight of the entire structure. The material models are described in detail in Section 4.3. All computations were performed with the commercial finite element code ABAQUS, Version 5.3 (ABAQUS, 1993b).

Gusset plates are welded between the upper and lower rings of the ring support girder to provide it with significant shear and bending resistance. To include the effect of the 32 gusset plates in the axisymmetric finite element model, we modeled them as a solid ring with an orthotropic material model and a reduced Young's modulus. The ring representing the gusset plate was assumed to have no stiffness in the hoop direction. The reduced stiffness in the axial and radial directions was obtained by multiplying Young's modulus of the actual material by the ratio of the actual area of the gusset plates to the area of the solid ring modeled in the axisymmetric finite element analyses.

Because the global axisymmetric analyses were performed before the design of the CS was finalized, there are two important differences between the CS as modeled in these analyses and in the final design. The first difference is that the CS was fabricated from SA516 Grade 70 steel rather than A36 steel represented in the analyses. SA516 has a slightly higher yield (258 MPa [38 ksi] compared to 245 MPa [36 ksi] for the A36) and also a slightly higher ultimate strength (476 MPa [70 ksi] compared to 408 MPa [60 ksi] for A36) (Hucek, 1985). Because the weaker A36 steel CS remained essentially elastic (i.e., only local yielding occurred) in these analyses, it is unlikely that the change in material will significantly affect the results. The other important difference lies in the geometry of the CS near the knuckle of the SCV. Figure 5-2 details the differences between the as-modeled and the final design geometry for the part of the CS adjacent to the knuckle. Note the gap at the top of the knuckle in the final design of the structure is nearly twice that of the model: 38 mm compared to 18 mm. The final design geometry near the knuckle is included in the local

axisymmetric analysis of the top head described later in Section 7.1.

5.2 Results – 18 mm Case

This section describes results for the case of a uniform 18 mm gap between the SCV model and the CS. In these analyses, the CS is modeled with A36 steel based on preliminary designs, but because it is designed to remain essentially elastic throughout the test, the response of the SCV model should not be much different for the CS constructed of SA516 Grade 70 steel in the final design.

5.2.1 Displacement History

Figure 5-3 and Figure 5-4 show the displacement histories at the boundary condition locations. The apex of the hemispherical dome on the top head and the bottom of the bottom hatch cover are the locations where the axisymmetric boundary conditions are applied. The vertical displacement as a function of internal pressure is plotted in Figure 5-3. The scaled design pressure (P_d) for the model is 0.78 MPa (113 psi). The vertical displacement of the apex of the hemispherical dome increases linearly until after $3 P_d$ where the slope increases. At $5 P_d$, when the vertical displacement is just over 15 mm, the effect of the CS becomes apparent as the slope decreases significantly. Above $7 P_d$, the slope increases once again due to yielding in the top head. At $10 P_d$ the maximum displacement at the apex is approximately 46 mm. The bottom hatch cover displaces linearly downward such that the displacement at $10 P_d$ is approximately -2 mm. The horizontal displacement in Figure 5-4 at the bottom of the ring support girder is relatively small in comparison to the displacements shown in Figure 5-3. The displacement is linear until contact initiates at just over $5 P_d$, where it continues to increase to a maximum of nearly 0.4 mm at $10 P_d$.

5.2.2 Contact History

Figure 5-5 and Figure 5-6 show the gap closure history as a function of the meridional distance along the SCV wall (distance along the shell reference line) starting with $x = 0$ at the bottom of the lower cylindrical shell and ending at the top of the knuckle (refer to Figure 5-1). The initial gap from the lower conical section to the knuckle region is 18 mm. When contact has occurred the gap distance is equal to zero.

Figure 5-5 shows data for $4 P_d$, $5.1 P_d$ and $6 P_d$. The gap closes rapidly from $P = 4 P_d$ until first contact occurs in the knuckle region at $P = 5.1 P_d$. As will be shown later, this is due primarily to the growth of plastic strain in the middle and upper conical sections as well as in the knuckle region. Immediately after contact in the knuckle region, contact occurs in the upper conical section, and at $6 P_d$, contact has also occurred in the middle conical section. By $8 P_d$, contact has also spread to the lower conical section (Figure 5-6). When the internal pressure reaches $10 P_d$ contact has initiated in the spherical section, and has propagated significantly in all other areas, although no contact occurs at any of the stiffeners.

5.2.3 Strain History - SCV

Figure 5-7 shows the hoop and meridional strains at the middle surface for two pressures, $5.1 P_d$ and $8 P_d$, as a function of distance along the SCV wall up to the top of the middle conical section. At first contact, $5.1 P_d$, the strain field is dominated by hoop strains in free field regions away from any discontinuities. This shows that the deformation in this region is dominated by radial expansion. At $8 P_d$, the meridional strain in the material just below the material interface is in compression, and the distribution of hoop strain is nearly constant in both the lower and the middle conical sections due to the constraint imposed by the CS. At $10 P_d$ (Figure 5-8), the hoop and meridional strains continue to follow the same trend as in Figure 5-7. The maximum meridional strain at this pressure is approximately 2.1% at the stiffener while the maximum hoop strain is approximately 1.9% in the lower cylindrical shell.

Figure 5-9 shows the membrane hoop and meridional strain components at $5.1 P_d$ and $8 P_d$ as a function of distance for the SCV wall beginning at the bottom of the upper conical section ($x = 0$) and ending at the top of the knuckle. At $5.1 P_d$ the maximum hoop strain is roughly 2% and occurs in the knuckle region, while the minimum meridional strain is in the knuckle and shows a compressive strain of approximately -0.7%. In the upper conical section, hoop strains dominate the meridional component with a local maximum occurring in the middle of the upper conical section. The hoop and meridional components of strain are nearly equal in the spherical section which is consistent with the theoretical elastic stress field in a pressurized sphere – uniform tensile stresses in all directions (Gere and

Timoshenko, 1984). At $8 P_d$ the maximum value of hoop strain remains in the knuckle and has increased to 2.5% and the meridional component has decreased slightly to -0.8% (compression) in the same location. The maximum hoop strain in the upper conical section has not increased significantly due to the restraint of the CS in this location, although the magnitudes of the hoop strain near the top and bottom of the upper conical section have increased such that the distribution is nearly uniform throughout the upper conical section. Plasticity has begun to govern the strain field in the spherical section as shown by the significant increase in hoop strain relative to the meridional component. The meridional component increased only slightly throughout the entire domain with the maximum value of 0.5% occurring at the stiffener. Figure 5-10 shows the hoop and meridional components at $10 P_d$. The hoop strains have not increased significantly in the upper conical section due to the presence of the CS. At the stiffener location and above it in the spherical section where contact has not yet occurred, the hoop strains have increased significantly although the maximum for the entire domain is about 3% in the knuckle. The meridional strains have generally increased except at the knuckle where they have decreased to roughly -1% (compression).

To illustrate the compressive strains in the knuckle, Figure 5-11 shows the hoop and meridional stress history at the middle surface for an element in the knuckle. The dominant tensile hoop stress causes a compressive strain in the meridional direction. This is a Poisson's effect, which can be easily verified using Hooke's law for plane stress (Gere and Timoshenko, 1984).

Figure 5-12 shows the definitions of the different sections in the top head. Figure 5-13 shows the meridional and hoop components of strain as a function of distance from the bottom of the cylindrical portion of the top head just above the knuckle up to the apex of the dome for $5.1 P_d$ and $8 P_d$. At both pressures, the largest hoop strains occur in the lower cylindrical section where it connects to the knuckle. The top flange limits the hoop strains to nearly zero for both load steps but creates a meridional strain concentration in the element immediately below the top flange that is over 1.2% at $5.1 P_d$ and over 2% at $8 P_d$. The rest of the meridional strain field at $5.1 P_d$ consists of relatively small strains with uniform distribution. At $8 P_d$, significant meridional strains occur in transition from the cylindrical portion of the top head to the hemispherical

dome. Here the meridional component is in tension due to membrane stretching from the uplift of the dome. The hoop component is in compression as a result of this section being pulled radially inward by the dome. Figure 5-14 shows the meridional and hoop components at $10 P_d$. Here the radial compression effect is even more pronounced although the maximum values for each component remain in the cylindrical section between the knuckle and the top flange. Figure 5-15 shows the equivalent plastic *membrane* (middle surface) strain as a function of the meridional distance along the SCV wall from the bottom of the lower cylindrical shell to the top of the knuckle for three different internal pressures. The figure shows that significant plastic strains do not develop in the SCV wall until after $4 P_d$. The plastic membrane strain in the SCV wall grows considerably from $4 P_d$ to $5.1 P_d$, the pressure where contact first occurs. The maximum membrane strain in the SCV wall is approximately 1.8%. The rate of increase in membrane strain with increasing pressure has obviously been slowed by the interaction with the CS. Figure 5-16 shows the plastic membrane strain at two higher internal pressures. At $8 P_d$ the maximum strain in the SCV wall is approximately 2.6% just below the knuckle. At $10 P_d$ the maximum plastic strain in the SCV wall is about 3.1% at the same location. Uniform distribution occurs in the lower, middle, and upper conical sections at both pressures due to the widespread contact in these areas.

Figure 5-17 shows the equivalent plastic *surface* strains as function of distance along the SCV wall. At $5.1 P_d$ the maximum plastic surface strain of 3.3% occurs on the exterior surface just below the knuckle region. The maximum plastic surface strain at $10 P_d$ has shifted to the location just below the 12.5 mm stiffener where the top of the lower cylindrical section meets the bottom of the lower conical section. The magnitude of this interior surface strain is about 7%. Large differences in magnitude between the interior and exterior surface strains indicate bending due to a discontinuity such as a stiffener.

Figure 5-18 shows the equivalent plastic membrane strain as a function of meridional distance starting with $x = 0$ at the top of the knuckle up to the apex of the top head for three internal pressures. At $4 P_d$ there is a small amount of plastic strain due to the thickness and curvature discontinuity at the knuckle interface. At $5.1 P_d$, the strain has significantly increased to approximately 1.5% because of the discontinuity at the knuckle. At this pressure the maximum plastic strain in

the transition from the cylindrical region of the top head to the hemispherical dome is about 0.05%. At $6 P_d$, the strain has increased slightly near the knuckle discontinuity, and the strain in the transition region is more than 0.2%. Figure 5-19 shows data for the same locations for $8 P_d$ and $10 P_d$. At $8 P_d$ plastic strains have developed in each region except for the top flange. At $10 P_d$ the strain is more than 3.3% just above the knuckle, nearly 1% in the cylindrical portion above the top flange, approximately 1.5% in the transition region from the cylindrical portion to the hemispherical dome, and over 4% at the apex of the hemispherical dome.

In Figure 5-20 the plastic surface strains are plotted along the meridional distance from the top of the knuckle to the apex of the hemispherical dome. At $5.1 P_d$ the maximum surface strain is on the interior surface in the region adjacent to the top flange and has a magnitude of nearly 5%. At $10 P_d$, the strain at the same location has nearly doubled to more than 9%. Plastic surface strain has also accumulated in the cylindrical portion above the top flange, in the transition region from the cylinder to the dome, and in the dome itself. The character of the bending changes from the cylindrical section, where the exterior surface has the higher strains, to the transition region, where the interior surface strains are higher, to the hemispherical dome, where the exterior surface strains are higher again.

Figure 5-21 shows the equivalent plastic membrane strain history for one element from each of the four stiffeners. Locations of the stiffeners are shown in Figure 2-3. The elements plotted are those with the highest plastic strain at $10 P_d$. The element with the highest plastic strain was also the element located on the innermost ring of the stiffener, i.e., the element at the smallest radius. The 19 mm stiffener in the upper conical section is clearly the worst case, although the maximum strain at $10 P_d$ is just under 1.5%. This stiffener yields at $4.9 P_d$, well before the other stiffeners, and strain increases at a greater rate after yielding. The other 19 mm stiffener has the second highest plastic strain at $10 P_d$ although it does not yield until about $8.0 P_d$. The 9.5 mm stiffener yields at $6.3 P_d$, but its maximum plastic strain never exceeds 1%. The 12.5 mm stiffener yields the latest of all, at about $8 P_d$, and reaches a maximum plastic strain of only 0.6% at $10 P_d$.

Figure 5-22 shows the hoop and meridional components of strain for the element from Figure 5-21 with

the highest maximum plastic strain (element #1300 in the 19 mm stiffener in the upper conical section). The hoop component is in tension for the entire pressurization due to the radial expansion of the ring. The meridional component (in the horizontal direction) is in compression due to a Poisson's effect. Elements from the other stiffeners show similar behavior.

In Figure 5-23, the equivalent plastic strain and the hoop and axial components are plotted as a function of internal pressure for an element in the top flange. As with the stiffeners, this particular element was chosen because it had the highest plastic strain at $10 P_d$ relative to the other elements in the top flange. This element was located on the inside ring on the bottom of the top flange. The hoop component is in tension because of the radial expansion of the cylindrical portion of the top head, and the axial component is in compression due to Poisson's effect. The hoop strains are linear up to about $4.0 P_d$ and then increase more rapidly due to yielding in the cylindrical section located just below the flange. The rate of increase in hoop strain then decreases again from $5.1 P_d$ to about $8.5 P_d$ due to the spread of contact along the SCV wall. Finally, the hoop strain increases more rapidly once again above $8.5 P_d$ due to yielding of the flange. Analogous changes in slope occur in the compressional meridional strains. Plastic strains in this element are small relative to other locations in the model; the maximum value at $10 P_d$ is less than 0.3%.

5.2.4 Strain History - CS

Figure 5-24 shows the equivalent plastic strains and the hoop and axial components of strain for the element with the highest plastic strain at $10 P_d$. This element is located in the top row of elements on the inside surface of the CS adjacent to the knuckle. This element did not yield until nearly $7.7 P_d$ and reached a maximum strain of roughly 0.6%. The behavior of the axial and hoop components was similar to the behavior observed in the top flange. No other locations in the CS developed plastic strains, even up to a pressure of $10 P_d$.

5.2.5 High Plastic Strain Locations

Figure 5-25 compares the equivalent plastic membrane strain history for two elements: one from the spherical section and the element at the apex of the top head. These elements were chosen because of their high plastic membrane strains relative to other elements and also because they show little or no bending behavior.

The element from the spherical section yields at roughly $4.5 P_d$ but does not begin to accumulate any appreciable plastic strain until about $7 P_d$. After $8.6 P_d$, when this particular element comes in contact with the CS, it accumulates very little additional plastic strain, for a total of approximately 2.5% at $10 P_d$. The element at the apex of the top head yields late relative to the first element, after $7 P_d$, but accumulates plastic strain much more quickly, reaching a value of 4.7% at $10 P_d$, which is the maximum plastic membrane strain magnitude for the entire structure.

Figure 5-26 shows the equivalent plastic *surface* strain history for three elements: the element at the transition from the lower cylindrical shell to the lower conical section, the element immediately below the top flange, and the element immediately above the knuckle. Note that the first two elements are evaluated at the interior surface of the SCV wall and the last one is evaluated at the exterior surface. These elements were chosen because they have high magnitudes of surface strain as well as large differences between the interior and exterior surface values, indicating bending-dominated behavior. The interior of the element from the lower conical section adjacent to the lower cylindrical shell yields at roughly $3.5 P_d$, but because it is composed of the higher yield material and is relatively close to the overly stiff bottom head, it never contacts the CS and thus continues to accumulate plastic strain. This element seems to be pivoting radially outward from the point where the curvature changes from cylindrical to conical, because the cylindrical section is stiffer.

The interior surface of the element immediately below the top flange reaches a maximum surface strain of over 9%, which is the maximum plastic surface strain for the entire structure. This element never contacts the CS, although the effect of global contact on this element at $5 P_d$ is evident. This element attaches to the extremely stiff top flange, and as the cylindrical section between the knuckle and the top flange expands radially outward this element bends outward, accumulating a large amount of plastic strain on the inside surface. However, the element immediately above the knuckle does not show similar behavior. In this element, the exterior surface shows the higher strain. Because the knuckle displaces radially outward much more than the top flange, the element adjacent to the knuckle is pulled outward such that its outside surface is in tension. This element reaches a maximum value of roughly 8.5%, which is the maximum exterior surface strain reached in the structure.

5.3 Results - 34 mm Case

Contact first occurs for the 34 mm case at $5.5 P_d$ (compared with $5.1 P_d$ for the 18 mm case) in the upper conical section. The strains in the middle conical section, knuckle, and lower conical section continue to increase rapidly until contact occurs in these areas at $5.7 P_d$, $6.1 P_d$, and $7.4 P_d$, respectively. Unlike the 18 mm case, the plastic membrane strain in the spherical section is highest at higher pressures, reaching a maximum of approximately 5.5% at $10 P_d$. For the surface plastic strains, the behavior is similar to the 18 mm case. The cylindrical section just below the top flange has the highest value, a maximum of approximately 12% at $10 P_d$, because the outward expansion of the cylindrical section is restrained by the stiffer top flange.

Figure 5-27 shows the gap closure history as a function of the meridional distance along the SCV wall starting with $x = 0$ at the bottom of the lower cylindrical shell and ending at the top of the knuckle (same as Figure 5-5 and Figure 5-6 for the 18 mm gap) at $5.5 P_d$, $8 P_d$, and $10 P_d$. The first location of contact is in the upper conical section at $5.5 P_d$, followed by the middle conical section at $5.7 P_d$, followed by the knuckle at $6.1 P_d$. By $8 P_d$, contact is widespread in the lower, middle, and upper conical sections (similar to Figure 5-15 and Figure 5-16 for the 18 mm gap). By $10 P_d$, the area of contact has continued to spread in these areas, and contact has also initiated in the spherical section.

Figure 5-28 shows the equivalent plastic *membrane* strain as a function of distance along the SCV wall for three internal pressures (5.5 , 8 , and $10 P_d$). The upper conical section has the highest magnitude of membrane strain at first contact, approximately 3.4%, but by $8 P_d$ the knuckle has the highest magnitude of strain, approximately 4.8%. At $10 P_d$ the strain in the knuckle has increased to over 5.5%, the strain in the upper conical section has a maximum value of 4.4%, and the maximum strain in the middle conical section is slightly over 3.6%. The distributions of plastic strains at all pressures above $5.5 P_d$ are qualitatively similar to the 18 mm gap analysis, but at a magnitude approximately twice as large. However, none of the strains is large enough to indicate global failure before $10 P_d$.

Figure 5-29 compares the equivalent plastic membrane strain history for two elements: one from the spherical section and the element at the apex of the top head (same as Figure 5-25 for the 18 mm case). These elements were chosen because of their high plastic membrane strains relative to other elements and also because they show little or no bending behavior. The element from the spherical section yields after $4.5 P_d$ and quickly accumulates plastic strain up to $9.1 P_d$, where it contacts the CS and the growth of plastic strain is greatly reduced. The behavior of the element at the apex of the top head is nearly identical to the same element in the 18 mm case. After yielding at roughly $7 P_d$, the element rapidly accumulates 4.5% plastic strain by $10 P_d$.

Figure 5-30 shows the plastic *surface* strain for three elements: the element at the transition from the lower cylindrical shell to the lower conical section, the element immediately below the top flange, and the element immediately above the knuckle. These are the same three elements that were discussed for the 18 mm case in Figure 5-26, and they show similar behavior. The first location, the interior of the element from the lower conical section adjacent to the lower cylindrical shell, reaches a maximum strain of just under 9% at $10 P_d$, compared to 7.5% for the 18 mm case. The next location, the interior surface of the element immediately below the top flange, reaches a maximum surface strain of over 12%, compared to over 9% for the

18 mm case. This is also the location of maximum plastic surface strain for the entire structure. The drastic slope change at $6 P_d$ is caused by global contact between the SCV and the CS, although the element itself never contacts the CS. The larger 34 mm gap allows this element to reach over 11% plastic surface strain at contact compared to less than 5% for the 18 mm case. The behavior at the last location is similar to the same element in the 18 mm case. The exterior surface of this element reaches a maximum of just over 9% strain compared to almost 8.5% for the 18 mm case.

5.4 Summary

The axisymmetric analysis with a uniform 34 mm gap indicated that contact would occur at $5.5 P_d$, compared to $5.1 P_d$ indicated by the 18 mm gap analysis. Above $5.5 P_d$, the maximum strains in the part of the SCV wall shielded by the CS for the 34 mm gap were roughly twice those for the 18 mm gap, a direct consequence of the fact that the gap is approximated twice the size. However, in neither case did the level of strains indicate global axisymmetric failure of the vessel even at $10 P_d$. Strains in the top head are nearly the same for both cases. It must be noted that nothing can be inferred from these analyses about non-axisymmetric strain levels, i.e., the local strain concentrations near the equipment hatch, which may be strongly affected by the local gap dimension.

6. Global Three-Dimensional Shell (G3DS) Analysis

A global three-dimensional shell analysis was the only way to assess the steel containment vessel (SCV) behavior including the equipment hatch explicitly in the model. In addition to providing insight into global model behavior, this model also provided the boundary conditions for the local three-dimensional models described in Section 7.

6.1 Finite Element Model Description

The finite element model of the SCV and contact structure (CS) for the G3DS model appears in Figure 6-1. The half-symmetry model used approximately 4800 four-node reduced integration shell elements with finite membrane strain capability (ABAQUS S4R elements). The only non-axisymmetric detail of the SCV/CS assembly and this finite element model is the equipment hatch. Symmetric boundary conditions were imposed on all nodes lying in the vertical (x - y) plane passing through the centerline of the equipment hatch, and vertical displacements were constrained at the support locations on the underside of the ring support girder. The loading consisted of gravity and internal pressure, and the analysis ran until it failed to converge at approximately 12.7 MPa internal pressure or slightly over $16.3 P_d$. The nominal gap between the SCV and the CS was 18 mm. For this model, the available small sliding formulation was deemed appropriate because the relative sliding of the SCV and CS was assumed to be small. The friction coefficient, discussed previously in Section 4.2.1, was $\mu=0.2$. Computations for this model were performed with ABAQUS/Standard, Version 5.4 (1994).

The thickened equipment hatch insert plate was constructed such that it is flush with the inside surface of the SCV. The resulting thickness eccentricity poses a problem when using shell elements in ABAQUS because there is no way to explicitly model a shell with uneven material distribution about a reference line. A simple elastic test case showed that using the *SHELL SECTION, COMPOSITE option in ABAQUS is an accurate way of implicitly modeling the eccentricity at the equipment hatch insert plate¹⁶. The equipment

hatch insert plate was modeled as a composite shell with three layers. As shown in Figure 6-2, the eccentricity was introduced by making the middle layer the same thickness (t_w) as the adjacent material and then placing two layers with the same thickness on either side, such that the total thickness of the middle and outer layers is equal to the insert plate thickness (t_p). The middle and outside layers were given the modulus of elasticity for the equipment hatch insert plate (measured from the Hitachi tensile tests in Appendix B), $E_{plate} \sim 216 \times 10^9$ Pa, while the inner composite layer was given a dummy modulus of $E_{dummy} \sim 1$ Pa. This formulation makes the stiffness of the inner layer of the composite shell negligible with respect to the other two layers.

Because of the eccentricity at the insert plate, the gap between the insert plate in the SCV model and the as-designed CS is reduced considerably from 18 mm to approximately 9 mm. However, because the contact algorithm uses the centerline of both the composite shells in the SCV insert plate and the regular shells in the CS as the reference, the eccentricity formulation described above does not represent the smaller gap. The gap between the insert plate and the CS in the finite element model remains 18 mm rather than 9 mm.

As with the axisymmetric model described in Section 5.1, there were two important changes made late in the design of the CS that were not incorporated in this model. The CS material and its geometry near the knuckle of the SCV in the global three-dimensional shell model were the same as in the axisymmetric model (see Figure 5-2 for knuckle details). It is unlikely that the difference in materials would significantly affect the results. However, the geometry near the knuckle is especially important and is modeled more accurately and completely in a local axisymmetric continuum model of the top head described in Section 7.1.

6.2 Results

Table 6-1 summarizes the yielding and contact events for the global three-dimensional shell analysis. Results for deformed shape, contact history, and high strain or critical areas are discussed in the following sections.

¹⁶ Carter, P.A., "Eccentricity Test Case," Sandia memorandum to V.K. Luk and M.F. Hessheimer, July 17, 1995.

Table 6-1. Summary of Yielding/Contact Events for Global 3-D Shell (G3DS) Model

Internal Pressure	Event
0 - 2.3 MPa	Elastic behavior
2.3 MPa	Local yielding in top/bottom of E/H sleeve at attachment to insert plate
2.3 MPa	Local yielding at middle conical section attachment to E/H insert plate
2.7 MPa	Yielding in knuckle
2.8 MPa	Local yielding at bottom of E/H insert plate
3.0 MPa	Local yielding in upper conical section above E/H
3.1 MPa	Yielding in middle conical section around circumference
3.4 MPa	Yielding in upper conical section around circumference
3.7 MPa	Yielding in lower conical section near insert plate
3.9 MPa	Yielding in lower conical section around circumference
4.1 MPa	Contact initiates in the SCV in the upper conical section and knuckle
4.1 MPa	Circumferential contact in upper conical section
4.3 MPa	Circumferential contact in middle conical section
4.7 MPa	Yielding in lower cylindrical shell around circumference
5.1 MPa	Yielding in dome of top head
5.3 MPa	Circumferential contact in lower conical section
5.5 MPa	Yielding in spherical section (away from knuckle)
6.6 MPa	Contact initiates in spherical section
11.3 MPa	Circumferential contact in lower cylindrical shell

6.2.1 Displacements

Figure 6-3 shows the deformed shape of the SCV at six different pressure levels. All displacements have been magnified by a factor of five. For clarity, the CS, ring support girders, and gusset plates are not shown. At 3 MPa, when only localized yielding has occurred, very little deformation is discernible. At 4.1 MPa, when contact first occurs, there is noticeable deformation in the upper and middle conical sections. The effect of the stiffeners is evident in the upper conical section as it tries to expand outward but is restrained by two 19 mm stiffeners. The knuckle shows deformation in both the outward (radial) and vertical directions, while the top head and top head flange deform nearly exclusively in the vertical direction. The equipment hatch also appears to be rotating outward and downward at this

pressure. By 6 MPa, most of the upper and middle conical sections are contacting the CS. The outward expansion of the lower cylindrical shell is now apparent. At 8 MPa it is clear that the CS is arresting further radial expansion of most of the SCV. The apex and the cylindrical portion of the top head, which are not shielded by the CS, are showing excessive amounts of deformation. At 10 MPa, which is nearly 13 multiples of the design pressure, the only locations where further deformations are clear are the top head and the lower cylindrical shell.

Vertical displacement at the apex of the top head and horizontal displacement at the center of the equipment hatch cover are shown in Figure 6-4. Displacements at both locations are linear until approximately 3.0 MPa. From 3.0 MPa to approximately 4.0 MPa, the vertical

displacement of the apex increases more rapidly due to yielding in the SCV wall. When contact initiates in the knuckle region and upper conical section, the meridional strains are constrained so the rate of vertical displacement at the apex decreases significantly. At 5.1 MPa, yielding begins in the top head so the vertical displacement at the apex increases rapidly. Similarly, the horizontal displacement at the equipment hatch increases rapidly from approximately 3.1 to 5.5 MPa due to yielding in the lower and middle conical sections. Above 5.5 MPa, local contact occurs at the equipment hatch centerline thus restraining further radial growth.

6.2.2 Contact History

Figure 6-5 shows the progression of contact. Only the part of the SCV that is shielded by the CS is displayed. Dark areas indicate contact while light areas indicate no contact. The first plot shows contact initiating in the upper conical section and the knuckle. The area of contact has increased considerably at 5 MPa to include the middle conical section, and by 6 MPa contact includes the lower conical section. By 8 MPa, the spherical section has made uniform circumferential contact except near the upper 19 mm stiffener, which is still arresting the radial growth of the SCV. At 10 MPa, the only area of the SCV that has not contacted the CS is the lower cylindrical shell where the initial gap is well over 100 mm.

6.2.3 Strains

Figure 6-6 and Figure 6-7 show locations at which various components of free-field strains are discussed. These strains are plotted in Figure 6-8, Figure 6-9, and Figure 6-10. In all locations, the hoop strain increases rapidly when yielding occurs, and then becomes nearly constant when contact occurs. The highest level of hoop strain occurs in the upper conical section because the gap dimension is the same but the radius of the containment vessel is smaller than in the lower sections. Some bending is evident in Figure 6-9 as shown by the difference in interior and exterior strains near the material interface and in Figure 6-10 at the midheight of the upper conical shell.

Figure 6-11 shows transition areas at which strains are plotted in Figure 6-12 through Figure 6-14. Of particular interest in these areas near stiffeners are the meridional strains at the interior and exterior surfaces. Differences in the strains at the two surfaces indicates the amount of bending strain. Near the lower stiffeners (Figure 6-12), bending becomes quite pronounced above 5.1 MPa, after yielding in the lower cylindrical shell. However, the gap in this area is quite large, so contact does not occur until 11.3 MPa. Above this pressure, the bending strain is slightly reduced. At the material change interface (Figure 6-13), the bending strains are not as pronounced although bending is evident between 4.0 and 8 MPa. Above the latter pressure, local contact occurs with the CS so the bending strain is severely restricted. Similar bending behavior occurs at the middle stiffener as shown in Figure 6-14.

6.2.4 Critical Plastic Strain Areas

Contour plots of equivalent plastic strain indicated three locations with high strains that dictated further study. Figure 6-15 compares the three locations which consistently displayed the highest plastic strains throughout the history: (1) the junction of the equipment hatch insert plate and the material change interface; (2) the apex of the top head; and (3) the knuckle region. The element at the knuckle and at the material change interface near the insert plate yields at roughly the same time, but the element at the knuckle contacts first, thus the plastic strain for this element levels out earlier in the loading. Because both elements are eventually shielded by the CS, neither accumulates nearly as much plastic strain as the apex of the top head. The apex yields at 5.1 MPa, compared to 2.5 MPa for the other two locations, but the amount of plastic strain quickly surpasses that accumulated at the other two locations, reaching a value of nearly 40% before the analysis fails to converge at just over 12.7 MPa. To assess the importance of these critical areas, refined models for both the top head, including the knuckle, and the area near the equipment hatch insert plate were created and are discussed in Section 7.

7. Detailed Local Analyses

Local analyses of the top head and the area around the equipment hatch were performed in order to incorporate more refined meshes in areas of high strain. In each case, boundary conditions on the edge of the refined local mesh were obtained from the global three-dimensional shell (G3DS) analysis described in Section 6.

The local submodel of the top head is an axisymmetric model with a fine mesh of continuum elements in the shell wall in order to more accurately model the thick knuckle and flange regions. It also incorporates the final design geometry of the contact structure (CS) in this area.

Two local submodels of the equipment hatch area were developed, both with three-dimensional shell elements. The first model is based on exactly the same geometry as that in global three-dimensional shell model. The only difference is that the mesh near the thickened reinforcement plate around the equipment hatch is significantly refined. The second submodel uses the same refined mesh but also incorporates an approximation of wall thinning discovered during on-site inspection of the steel containment vessel (SCV) model. Neither of these submodels utilized as-built information on gap size.

All material properties in these models were obtained from the uniaxial test data as described in Section 4.3.

7.1 Top Head Including Knuckle Region (LTHAXC)

One critical area requiring further study as indicated by the global models was the top head region including the knuckle. For this area, a local axisymmetric continuum model was created that included the most recent as-designed geometry of both the SCV and the CS from the top head apex down to the upper 19 mm stiffener.

7.1.1 Finite Element Model Description

Figure 7-1 shows the Local Top Head Axisymmetric Continuum Model. The model used 7200 four-node reduced integration, axisymmetric continuum elements (ABAQUS CAX4R elements) and five two-node thin or thick linear shell elements (ABAQUS SAX1 elements).

Axisymmetric boundary conditions were imposed at the apex of the top head. At the lower bound of the model, rotations and displacements from the G3DS model were applied to the shell nodes in a manner similar to the *SUBMODEL option in ABAQUS. However, ABAQUS does not allow the submodel option to be used when changing from a three-dimensional model to a two-dimensional axisymmetric model, so the process was conducted manually. The displacement and rotation histories from the appropriate nodes on the global shell model were applied with the *USER SUBROUTINE option, which provides the user with a way to prescribe the magnitude of any degree of freedom using FORTRAN code. Multi-point constraints were used to transition from the shell elements to the continuum elements. As with the other models, the loading consisted of internal pressure and gravity. The contact definition for this model was basically the same as the previous models (the coefficient of friction was $\mu = 0.2$) except that the small sliding formulation was not specified. For this case, ABAQUS defaults to a finite sliding formulation, which allows arbitrary separation, sliding, and rotation of the surfaces.

As mentioned in Section 5.1 and shown in Figure 5-1, the design of the CS was changed after the global axisymmetric and three-dimensional shell models were completed. However, the local continuum model of the top head described in this section includes those design modifications. Because continuum elements were used throughout the model, the geometry was more accurately modeled, especially near the top head flange and the knuckle.

7.1.2 Displacements

Figure 7-2 shows the deformation of the top head submodel. The first three plots are the deformed shape of the entire model at three different internal pressures, while the last six are close-ups of the knuckle/top head flange region with some additional pressure steps included. The displacements are *not* magnified. First contact occurs at 3.2 MPa at the knuckle as it expands radially outward to meet the corner of the CS. At 6 MPa bending of the cylindrical section of the top head from the bottom of the top head flange is apparent, and at 8 MPa bending around the top of the top head

flange is beginning. The vertical growth of the dome is also significant at 8 MPa. Note that the top head flange shows almost no radial expansion at 8 MPa. The overly stiff behavior of the top head flange and the rapid radial expansion of the knuckle create bending locations with significant plastic strains (Section 7.3.4). Figure 7-3 shows displacement and strain locations in top head.

Vertical displacement of the apex of the dome is plotted in Figure 7-4. This displacement is nearly identical to the same displacement that was obtained from the G3DS model (Figure 6-4). Because the top head submodel has a very fine mesh and therefore simulates more flexibility than the global model, the internal pressure reaches a maximum value of only 12.1 MPa rather than the 12.7 MPa indicated in the global analysis, and the maximum displacement is higher at this pressure.

7.1.3 Strains

Results for strain components in the top head are plotted in Figure 7-5 to Figure 7-7 for the locations shown in the diagram in Figure 7-3. As noted previously, the difference in strains at the interior and exterior surfaces indicates the amount of bending strain. Thus significant bending strain is present just below the top head flange for pressures greater than 3.0 MPa as shown in Figure 7-5. Some bending strain is also evident just below the knuckle (Figure 7-6). In the spherical section, the hoop and meridional components are nearly equal until significant yielding occurs at 5.4 MPa. Above 7.0 MPa, these strain components are significantly higher than those computed in the global three-dimensional shell analysis for any of the other free-field areas.

7.1.4 Critical Plastic Strain Areas

Figure 7-8 plots the strains from the critical locations from the top head submodel as a function of internal pressure. The five locations can be broken down into three areas: the apex of the top head, the top head flange, and the knuckle. After 8 MPa, all five locations show similar strain histories except for the element below the knuckle. The primary differences in the strain histories appear early in the loading.

The exterior surface of the apex of the top head yields late in the history at about 5 MPa compared to the other elements. Since this location is not protected by the

CS, the growth of plastic strain is rapid up to a maximum of over 34% at an internal pressure of 12 MPa.

The overly stiff behavior of the top head flange can probably be attributed to the mixed scaling of the SCV (1:4 ratio thickness; 1:10 ratio on overall size). This causes large bending strains in the elements just below and above the top flange on the interior surface. The element just above the top flange behaves similarly to the apex of the top head except that it yields sooner. The element just below the top flange accumulates more plastic strain early in the loading but otherwise behaves similarly to the first two elements.

The element at the interface between the top of the knuckle and the cylindrical section of the top head on the exterior surface accumulates still more plastic strain early in the loading but then appears to be temporarily affected by the CS at just over 3 MPa. The last location under consideration is the element at the interface between the bottom of the knuckle and the spherical section on the exterior surface. It accumulates more plastic strain than all the other elements until it contacts the CS at just over 3 MPa. The effect of the CS on this element is much more apparent as this element reaches a maximum strain of only 12% compared to nearly 34% for the apex and 24% for the other elements.

7.2 Equipment Hatch Area As Designed (LEHS)

The second critical area indicated by the G3DS analysis was the area near the thickened reinforcement plate around the equipment hatch. This area also includes the material change interface. This section describes a local submodel based on final design information.

7.2.1 Finite Element Model Description

The model (Figure 7-9) used 4800 four-node reduced integration shell elements with finite membrane strain capability (ABAQUS S4R elements). The boundary conditions were imposed using the *SUBMODEL option. Submodeling in ABAQUS is used to study a local part of a model with a refined mesh based on interpolation of the solution from an initial, G3DS onto the nodes on the appropriate parts of the boundary of the submodel. Figure 7-10 compares the global model mesh and the local submodel mesh. For this particular

analysis all nodes on the boundary of the submodel were “driven” by the results from the G3DS model. The loading consisted of gravity and internal pressure. The coefficient of friction used for this model was the same as in previous models, $\mu=0.2$. The eccentricity of the equipment hatch insert plate was also modeled as described in Section 6.1. Because this model uses results from the global model, the model was allowed to run up only to 12.7 MPa, the point where the global model failed to converge. Computations for this model were performed with ABAQUS, Version 5.4 (1994).

7.2.2 Contact History

Figure 7-11 shows the evolution of contact for the equipment hatch submodel. As before, black areas indicate contact, white areas indicate no contact. The elements on the border of the model are gray because they are “driven” nodes and so are not included in the contact algorithm. Contact first occurs at 4.2 MPa in the middle conical section. Contact propagates toward the insert plate at 5 MPa and by 6 MPa has contacted a large part of the insert plate and has spread to the lower conical section (below the material interface). At 8 MPa the contact is widespread throughout the model.

7.2.3 Critical Plastic Strain Area

This model was developed to study the junction of the equipment hatch insert plate and the material interface after the global model indicated potentially high strains in this area. Figure 7-12 compares the equivalent plastic membrane strains from the two models at the same location: the element in the 8.5 mm wall (middle conical section) that is adjacent to the equipment hatch insert plate and to the 9.0 mm wall (lower conical section). These elements are indicated in the figure. In the global model this element is approximately 60 mm by 30 mm in size; in the local submodel the element in the corresponding location is 11 mm by 11 mm. Qualitatively the behavior of the two elements is similar. Quantitatively, the element in the local submodel reaches strains nearly 50% higher than the global model: 9% in the submodel compared to approximately 6.5% in the global model. The difference is best explained by the submodel’s ability to measure more accurately the strain concentration because of its finer mesh.

7.3 Equipment Hatch As Built (LEHSTh)

The last analysis performed was used to study the effects of thinned areas near the junction of the equipment hatch insert plate and material change interface. This model is the same as the previously described local equipment hatch submodel, except that an approximation of wall thinning has been included.

7.3.1 Finite Element Model Description

Figure 7-13 shows the basic finite element model used to study the effects of thinning. The model is the same as the previous equipment hatch submodel except that the measured thicknesses near the junction of the equipment hatch insert plate and the material interface were input explicitly using the *NODAL THICKNESS option in ABAQUS, Version 5.5 (1995). This model was intended only to study the thinned area near the equipment hatch insert plate and so does not include any other as-built information.

The as-built measurements given in Appendix C indicate that the nominal thicknesses of the as-built SCV are 5% to 10% thicker than the designed configuration of the SCV, while two locations on either side of the equipment hatch insert plate are up to 22% thinner than the designed configuration on which all the finite element models are based. Changing the nominal thickness in the finite element submodel was not an option because the submodel used boundary conditions from the global model, which was based on the original, as-designed thicknesses. Accommodating the thinning in the finite element model, the measured thickness from the thinned areas from the SCV was converted to a percentage of the nominal measured thickness. Then these percentages were used to calculate the input thicknesses for the thinned locations in the finite element model.

7.3.2 Contact History

The contact behavior for this model is nearly the same as for the previously discussed equipment hatch submodel without wall thinning (Figure 7-11).

7.3.3 Strains

The four points near the equipment hatch reinforcement plate are depicted in Figure 7-14. Strains are plotted in

Figure 7-15 through Figure 7-17. All these points occur in the SGV480 material. As Figure 7-15 indicates, the maximum principal strain at 67.5 degrees is significantly higher than that at 45 degrees for internal pressures above 3 MPa. The strain at 45 degrees reaches its maximum value at around 4.0 MPa when contact occurs in this region. However, the strain at 67.5 degrees continues to grow above this pressure, eventually reaching nearly 7%. As Figure 7-16 illustrates, the meridional strains near the top of the reinforcement plate show substantial bending behavior. Both the exterior and the interior strain increase rapidly at around 3.8 MPa, but then increase more slowly after 4 MPa because contact has occurred. However, on both surfaces the meridional strain again increases rapidly, reaching a maximum of 3.5% at 12.7 MPa. The hoop strains just to the right of the reinforcement plate (plotted in Figure 7-17) also show some bending behavior after yielding has initiated (3.8 MPa).

Finally, strain components are plotted in Figure 7-18 at two more points near the reinforcement plate where pretest inspection revealed thinned wall material. Both

points are located in the SPV490 material below the material change interface indicated by the weld line. At these two points, both the meridional and the hoop strains are significantly higher than the points discussed above in the SGV480 material, particularly at Point 17 which is closer to the thickness transition at the edge of the reinforcement plate.

7.3.4 Critical Plastic Strain Areas

Figure 7-19 compares the critical strain area from this submodel with wall thinning to the global shell and the submodel without wall thinning. This is the same figure as Figure 7-12 with the data from the LEHSTh model added. Qualitatively each curve represents the same behavior: the element yields at between 3 and 4 MPa and accumulates plastic strain very quickly until it reaches the CS between 5 and 6 MPa. The primary difference between each curve is the amount of plastic strain accumulated prior to contact. The effect of the thinned section is apparent, as the slightly thicker and higher yield SPV490 material now shows the greatest accumulation of plastic strain.

8. Assessment of Potential Failure Modes

In this section we assess several possible failure modes of the steel containment vessel (SCV) model based on results of the finite element analyses. Failure of the SCV model is defined as inability to maintain pressure, due either to a catastrophic failure of the vessel or to a local tear that causes leakage. Because the SCV model has no bolted flanges or penetration covers, seal leakage is not considered. Furthermore, the SCV model has no known cracks of critical length that would lead to premature brittle fracture, so the discussion in this report is limited to ductile failure modes. The modes of failure that have been considered are buckling of the torispherical top head, global ductile rupture of the vessel (also referred to as plastic collapse), and local ductile tearing in areas of localized high strains.

8.1 Top Head Buckling

Considerable research has indicated from both experimental and analytical methods that some torispherical heads may be subject to non-axisymmetric buckling failures. Kalnins and Updike (1991) detail several publications on the subject. Torispherical heads with ratios of head thickness (t) to crown radius (L) less than 0.002 may be susceptible to buckling. Torispherical heads with t/L greater than 0.002 but less than 0.04 are much more likely to fail by axisymmetric plastic collapse (i.e., global ductile rupture) (Kalnins and Updike, 1991). For the SCV model,

$$\begin{aligned}t &= 6 \text{ mm} \\L &= 873 \text{ mm} \\t/L &= 0.0068 > 0.002\end{aligned}$$

Therefore, since t/L is significantly greater than 0.002, buckling of the torispherical top head was not considered a likely mode of failure.

8.2 Global Ductile Rupture

Global ductile rupture of a pressure vessel is an axisymmetric mode of failure that occurs when the free-field membrane von Mises stress reaches a critical value. The wall becomes thinner due to Poisson's ratio, but no alternate load path exists. Therefore, when the material cannot sufficiently harden to accommodate the additional stresses caused by the area reduction, it cannot carry the load. Rapid radial growth occurs and

is followed by global ductile rupture. This phenomenon is analogous to necking in uniaxial test specimens.

As described in Section 2.1 and shown in Figure 2-3, most of the SCV model is enclosed within the contact structure (CS). The CS is a thick steel shell that severely restrains radial growth of the SCV model. Therefore, in areas where the SCV model contacts the CS, global ductile rupture was not a likely mode of failure. However, because the top head above the knuckle is not enclosed within the CS, global ductile rupture must be considered in this region. Because global rupture is an axisymmetric failure mode, results from the axisymmetric continuum analysis of the top head region described in Section 7.1 are used here.

Figure 8-1 shows a schematic of the top head. Global ductile rupture of the top head could occur in the torispherical shell or in either of the two cylindrical shell regions. Finite element analysis results for radial growth are shown in Figure 8-2 for the crown of the torispherical shell and in Figure 8-3 for both cylindrical shell sections. In each case, generalized yielding of the section is indicated by the initial slope reduction of the curve, which occurs at approximately 4.0 MPa internal pressure for the torispherical shell and at 6.0 MPa for the cylindrical shells. However, in all sections, substantial capacity remains after initial yielding due to hardening of the material. The onset of global ductile rupture is indicated by substantial radial growth with a small change in internal pressure, i.e., the internal pressure at which the radial growth reaches an asymptotic value. The finite element results indicate that this pressure is slightly above 12.0 MPa in all three sections of the top head.

8.3 Local Ductile Failure

A failure mode more likely than global ductile rupture for a complicated structure such as the SCV model is a local failure caused by localized high strains. Local high strains may occur near stiffeners, thickness transitions, and changes in geometry. These may be intentional features of the design or as-built features. Failure in local areas is highly dependent on the exact geometry of local features in the actual model. Therefore, predictions are much less reliable than those for global failure modes.

Figure 8-4 shows a comparison of local critical strain areas from the finite element analyses. Only the results from two local submodels, the equipment hatch with wall thinning (LEHSTh) and the local top head continuum (LTHAXC) models are shown. For comparison of locations with differing material properties, the strains for each location were normalized by their true strain at maximum load from the Hitachi tensile tests. Therefore, a y -value of 1.0 corresponds to the strain at necking from that material's uniaxial tensile test. The raw (unnormalized) data are plotted in Figure 7-8 and Figure 7-19.

When the strains are normalized, the primary candidate for failure location becomes clear: the 9.0 mm wall section just below the material interface and near the equipment hatch insert plate shown by the long dashes in Figure 8-4. The primary reason that this particular location stands out is the difference in the ductility between the SPV490 steel and the SGV480 steel. The true strain at maximum load for the SPV490 material is approximately 10%; the true strain at maximum load for the SGV480 material is approximately 20%. Thus, the SPV490 material in the thinned section (9.0 mm nominal thickness, lower conical section) at an internal pressure of 5 MPa has reached a plastic strain that in the uniaxial-stress tensile test led to necking.

Continued deformation in the thinned section is "displacement controlled." That is, the boundary around the plastic domain in the thinned section interacts with the adjacent thicker stiffer elastic sections as a "cut out" or opening with a nominally fixed membrane load. Further increases in internal pressure cause the boundary around the thin section to expand similarly to the way an unreinforced cut out or opening in a pressure vessel expands. The expansion of the opening imposes additional strain on the yielding thinned section.

While the shell element mesh used in the LEHSTh model has some ability to represent locally accelerated thinning, it does not have the refinement necessary to track the strain localization on the length scale exhibited in the tensile test. The nature of the strain state, biaxial tension, is also important for failure prediction. The analysis indicates that the total strain in the thinned section is very nearly equal in two directions (circumferential and radial directions with respect to the edge of the equipment hatch insert plate

edge). Although a forming limit diagram for this material is not available, examination of a typical forming limit diagram for a low-carbon steel (Figure 8-5) shows the differences between the load path for a tensile test and the load path for the area under consideration (equal biaxial strain). In a typical tensile test, necking occurs at $2n$, where n is the strain-hardening exponent. Equal biaxial extension produces a neck at $1.3n$. Thus, significant localization of plastic flow with attendant tearing is expected in the thinned section when the normalized value of effective plastic strain reaches $(1.3/2.0) = 0.65$ or 65% of the necking strain from the tensile test. In Figure 8-4 this corresponds to approximately 4.5 MPa internal pressure for the location in the SPV490 material.

8.4 Conclusions

The pretest predictions of failure of the SCV model are dependent on details that were included in the analytical effort. In particular, local failure analyses are very dependent on as-built features incorporated into the analytical models. Results of a local analysis of the thinned section of the SCV wall near the equipment hatch reinforcement plate indicate that this area is the most vulnerable for failure. This analysis was based on an 18 mm gap in this region; it did not include the as-built gap dimensions which were somewhat larger. Given the early and rapid occurrence of plastic flow compared to other locations within the pressure vessel, the strains attained relative to the material's ductility, and the biaxial stress state, the finite element results indicate local ductile failure in the thinned section next to the equipment hatch insert plate near an internal pressure of 4.5 MPa. Global ductile rupture of the vessel is indicated in the top head at the much higher pressure of slightly more than 12 MPa.

An earlier failure at the equipment hatch or another location due to the presence of welding flaws or inclusions could not be ruled out because states of stress simultaneously produce plastic flow in at least four other locations in the pressure vessel (primarily the top head and knuckle regions). The weld metal and HAZ near the thinned areas introduce additional uncertainty. The yield strength and ductility of the weld metal is typically higher than the parent material, while the same properties in the HAZ are typically lower than the parent material. Brittle failure modes have not been considered in this analysis effort.

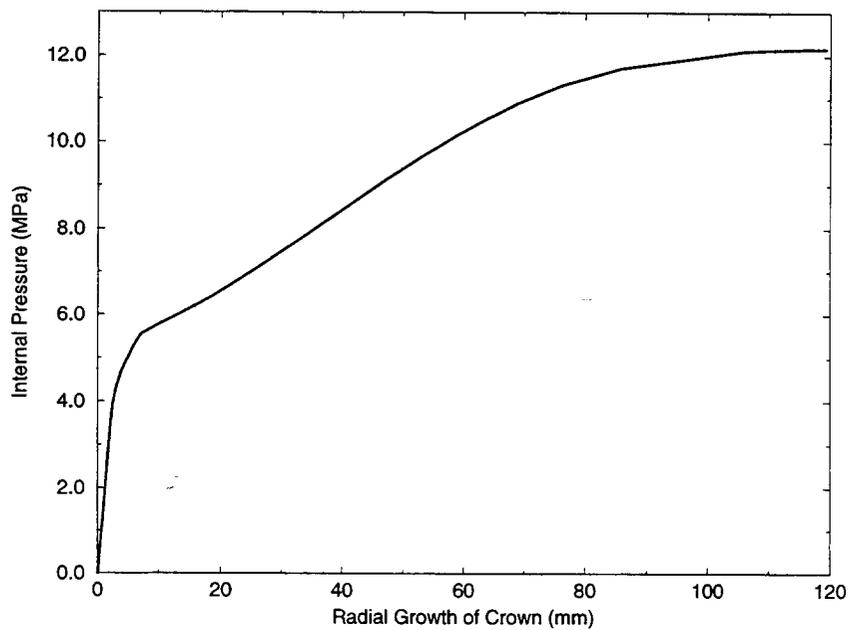

Figure 8-2. Radial growth at crown of torispherical head (see schematic Figure 8-1).

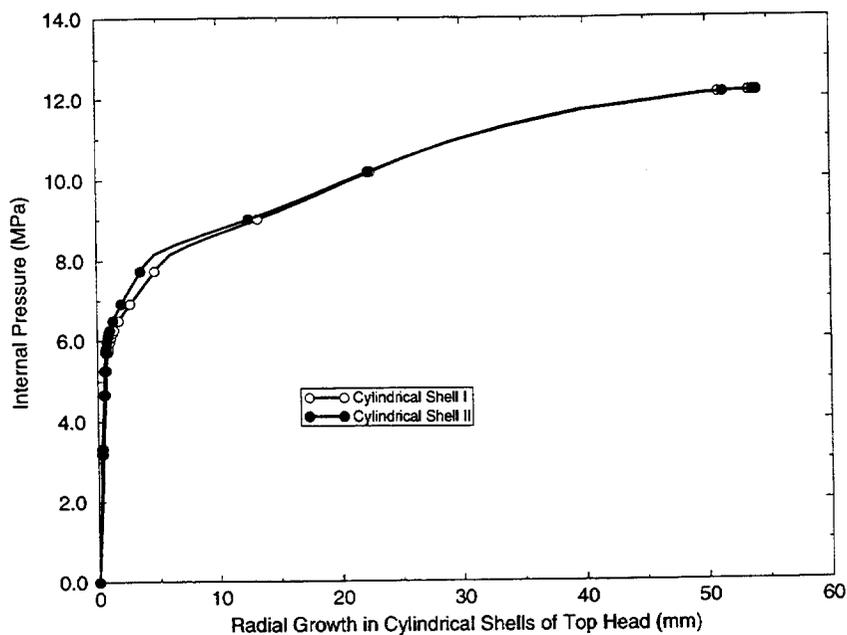

Figure 8-3. Radial growth in cylindrical sections of top head (shell sections shown in Figure 8-1).

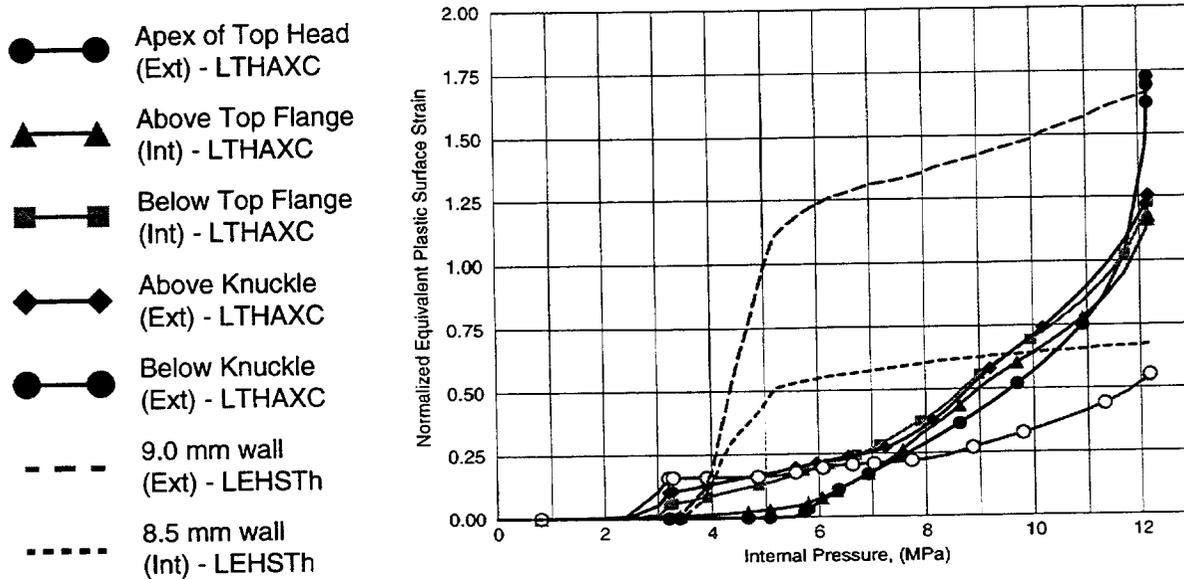

Figure 8-4. Normalized equivalent plastic strain from critical areas. Only critical areas from the local models are included because they are the most accurate. Strains have been normalized by each material's true strain at maximum load.

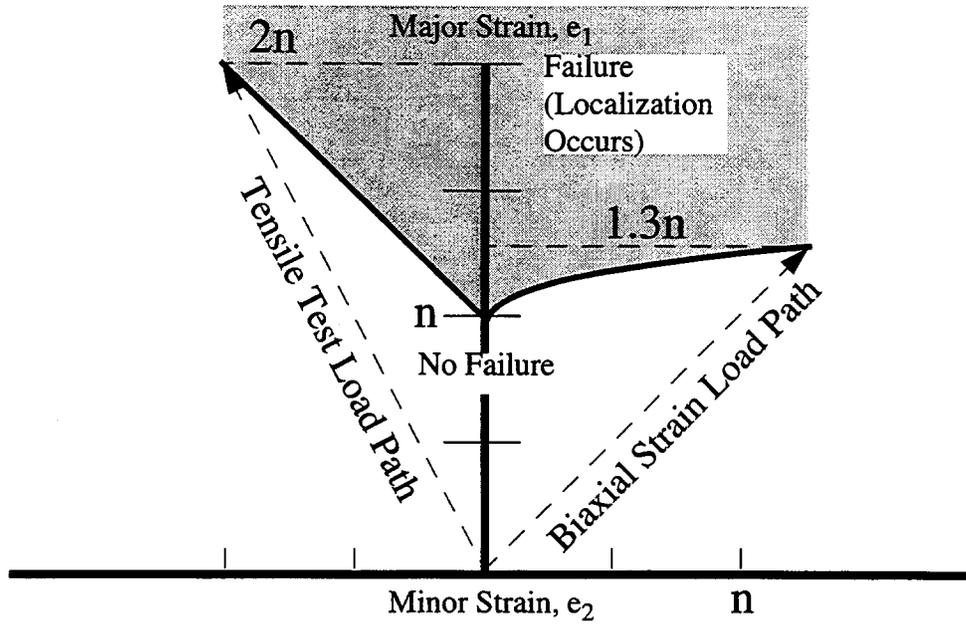

Figure 8-5. Typical forming limit diagram for low carbon steels. The strains below the curve are acceptable while those above the curve correspond to regions affected by local necking. Note the differences in major strain values between a tensile test load path and a biaxial strain load path (Hosford and Caddell, 1983).

9. Supplemental Computations for Design and Instrumentation Support

Several of the previously discussed finite element analyses were used to support the design of the model and the instrumentation system. This section describes additional analyses that were performed for these tasks.

9.1 SCV Model Design

Finite element computations were performed very early in the program to investigate the effects of the proposed mixed scaling (1:10 overall, 1:4 wall thickness). These included axisymmetric shell analysis of the unshielded, mixed-scale model¹⁷ as well as analysis of an unshielded full-scale containment^{18,19}. Comparison of these analyses showed that the proposed mixed-scale model would be an adequate representation of the overall behavior of the full-scale containment at a scaled pressure load. However, the relative increase in the wall thickness would have the effect of reducing the bending strains and would alter buckling characteristics in the top head. Therefore, this test should be regarded as a validation test for analysis methods that can then be used to analyze a full-scale containment vessel, but the test results cannot be directly applied to infer behavior of a full-scale containment.

9.2 Contact Structure

Early finite element axisymmetric shell analyses were also performed on the full-scale containment with a representation of a shield building in order to determine the effects that the inclusion of a contact structure (CS) would have on steel containment vessel (SCV) model behavior^{19,20,21,22,23}. These computations used a rigid

surface to model the CS in order to bound the problem and because no detailed information was available on the actual shield building. Table 9-1 summarizes the response of the shielded and unshielded containments in key locations. Results are presented at approximately 5% and 10% maximum strain because the original termination criteria were based on strain.

These results showed that the presence of a shield structure would have a significant effect on the behavior of the steel containment model. Maximum strains of 5% and 10% occurred at higher pressures in the shielded containment than in the unshielded. Furthermore, these maximum strains occur in different locations in the containment. In the shielded containment, the largest inelastic strains occurred in the top head, while in the unshielded containment the maximum strains occurred in the middle part of the conical section at lower pressure. Therefore, the inclusion of some type of CS in the scale model test was warranted.

Additional finite element analyses were performed to evaluate the thickness of the CS for the design effort²⁴. These axisymmetric shell analyses showed that a 32-mm thick CS constructed of A36 steel would not experience large plastic strains over the range of the test.

9.3 Instrumentation Holes

The presence of the CS presented some additional challenges for the instrumentation on the exterior surface of the SCV model. To measure bending response of the SCV model, strain gages were required on both the interior and exterior surfaces at the same location. During the initial stages of pressurization, the SCV was not in contact with the outer structure so the strain gages on the exterior surface functioned normally. However, once the SCV made contact with

Table 9-1. Behavior of Shielded and Unshielded MK-II Containment Vessel

Parameter	Unshielded	Shielded
Yield Pressure (MPa)	0.75	0.75
Pressure at First Contact (MPa)	N/A	0.84 (near top of equipment hatch)
At Approximately 5% Maximum Strain		
Pressure (MPa)	0.96	1.2
Maximum Strain at Knuckle (%)	5.2	2.2
Maximum Strain at Equipment Hatch (%)	2.9	0.6
Maximum Strain in Top Head (%)	-0.2	(5.2)
At Approximately 10% Maximum Strain		
Pressure (MPa)	1.25	1.4
Maximum Strain at Knuckle (%)	11	2.2
Maximum Strain at Equipment Hatch (%)	6.4	0.6
Maximum Strain in Top Head (%)	(6.1)	(8.9)
Note: All strain values are membrane strains. Meridional strains are denoted by enclosure in parentheses. All others are hoop strains.		

the CS, any strain gage in the area of contact eventually ceased to function. Therefore, measuring bending response beyond this point would not normally be possible. The solution to allow bending strain measurements to continue after contact has been established was to put small holes in the CS over a few of the gages on the exterior of the SCV as long as the holes were small enough that they would not affect the local behavior of the SCV model. Axisymmetric finite element analyses of a uniform load on a circular plate over a hole were performed to assess the effects such a hole in the CS would have on the strain in the SCV wall²⁵. Results of analyses for both 1.5-inch and 2.0-inch diameter holes in the contact structure indicate that the bending strains introduced in the SCV wall by contact with the hole would be on the order of 4% or 5% of the membrane strains. Furthermore, the deflection due to the bending is less than 0.2 mm even in the worst case. This amount of localized bulging represents less than 3% of the wall thickness.

9.4 Inner Support Ring Adequacy

During construction and instrumentation of the SCV model, an inner ring in the bottom head provided support for two technicians and instrumentation equipment. Instrumentation continued to be supported by this ring during the test. Finite element results for the radial deformation and stress state in this ring during pressurization showed that the SCV model exhibits very little radial expansion in this region and is sufficiently strong to sustain the anticipated loads²⁶. Furthermore, results of a simple closed-form analysis with both live and dead loads on the ring indicated that the ring was more than adequate to support the anticipated loads without significant vertical deflection.

10. Summary and Conclusions

This report documents the finite element analyses performed at SNL for support of design efforts and for pretest predictions of the behavior of a steel containment vessel (SCV) model to be tested in a joint program sponsored by Nuclear Power Engineering Corporation (NUPEC) of Japan and the Nuclear Regulatory Commission (NRC). The ABAQUS (1993b) general purpose finite element code was used for all structural analyses.

Preliminary axisymmetric analyses were used to characterize the behavior of the shielded mixed-scale model and for studies regarding the development of the finite element models to be used for later pretest predictions. As a result of these scoping computations, shell elements were used extensively in later models for prediction of model behavior during the test. In addition, the preliminary finite element analyses were used to perform a parametric study on the effects of friction between the SCV and the contact structure (CS). Results indicated that the magnitude of the friction coefficient between 0.1 and 0.5 had little effect on model behavior, although results from a frictionless analysis were substantially different. Because the SCV model and the CS are not lubricated surfaces, a friction coefficient of 0.20 was judged a reasonable assumption and used in all subsequent analyses. Finally, axisymmetric finite element analyses of uniaxial tensile test specimens were also used to extrapolate the material data provided by uniaxial tensile tests beyond maximum load to the stress ranges needed to extend the predictive analyses to the point of failure.

The structural analysis effort for pretest predictions of model behavior consisted of four basic finite element models with some analyses repeated with slight modifications. The results for first yield and for first contact for each of these analyses are summarized in Table 10-1. The first finite element model was a global axisymmetric shell element model. This model was run with two different gap dimensions (the nominal distance between the SCV and CS): 18 mm (the as-designed gap), designated as GAX18, and 34 mm (a worst-case-scenario gap), designated GAX34. All remaining analyses used the as-designed 18 mm gap dimension. The second model was a global three-dimensional shell element model (G3DS) whose only non-axisymmetric detail was the equipment hatch.

Results from this model called for further study in two areas: (1) the area near the junction of the material change interface and the equipment hatch insert plate, and (2) the top head including the knuckle. The third model was a local axisymmetric continuum element model of the CS and the top head area of the SCV from the apex extending down to the upper 19 mm stiffener (LTHAXC). The last model was a locally refined shell element submodel of a cut-out of the material change interface/equipment hatch insert plate junction from the three-dimensional shell element model. This model was first run with design parameters (LEHS) and then rerun later with a representation of as-built shell thicknesses when they became available (LEHSTh).

Pretest predictions of failure of the SCV model are highly dependent on details that were included in the analytical effort. In particular, local analyses are very dependent on as-built features incorporated into the analytical models. Results of a local analysis of the thinned section of the SCV wall near the equipment hatch reinforcement plate indicate that this area is the most likely for failure. This analysis did not include the as-built gap dimensions which were somewhat larger than the 18 mm used in the design. Given the early and rapid occurrence of plastic flow compared to other locations within the pressure vessel, the strains attained relative to the material's ductility, and the biaxial stress state, the finite element results indicate local ductile failure in the thinned section next to the equipment hatch insert plate near an internal pressure of 4.5 MPa. Global ductile rupture of the vessel is indicated in the top head at the much higher pressure of slightly more than 12 MPa.

An earlier failure at the equipment hatch or another location due to the presence of welding flaws or inclusions could not be ruled out because there are states of stress simultaneously producing plastic flow in at least four other locations in the pressure vessel (primarily the top head and knuckle regions). The weld metal and HAZ near the thinned areas introduce additional uncertainty. The yield strength and ductility of the weld metal is typically higher than the parent material, while the same properties in the HAZ are typically lower than the parent material. Brittle failure modes have not been considered in this analysis effort.

Table 10-1. Summary of Pretest Analyses

Model Description	First Yield		First Contact	
	Location	Pressure	Location	Pressure
Global Axisymmetric -- 18 mm Gap (GAX18)	Knuckle	2.2 MPa	Knuckle/upper conical section	4.0 MPa
Global Axisymmetric -- 34 mm Gap (GAX34)	Knuckle	2.2 MPa	Knuckle/upper conical section	4.0 MPa
Global 3-Dimensional Shells (G3DS)	E/H sleeve at attachment to insert plate	2.3 MPa	Knuckle/upper conical section	4.1 MPa
Local Axisymmetric Continuum of Top Head (LTHAXC)	Knuckle	2.0 MPa	Knuckle	3.2 MPa
Local 3-Dimensional Shells of Equipment Hatch Area (LEHS)	Middle conical section adjacent to insert plate	2.6 MPa	Middle conical section	4.2 MPa
Local 3-Dimensional Shells of Equipment Hatch Area with Thinning (LEHSTh)	Above thinned section adjacent to insert plate	2.2 MPa	Middle conical section	4.2 MPa

11. ABSTRACT (200 words or less)

As part of the containment integrity program jointly sponsored by the Nuclear Power Engineering Corporation (NUPEC) of Japan and the United States Nuclear Regulatory Commission (NRC), Sandia National Laboratories (SNL) conducted a high pressure test of a steel containment vessel (SCV) model, nominally based on a Japanese Improved MK-II boiling water reactor containment. The test included an external contact structure (CS), a steel shell that covered most of the SCV model with a gap between the two structures. One of the program objectives is to validate analytical methods used to predict the response of containment buildings subjected to severe accident pressures. This report describes the finite element analyses conducted by Sandia in support of the test program and for pretest prediction of model behavior. Preliminary calculations were performed to support model design, such as the effects of mixed scaling and the effects of including a contact structure in the test. Global response of the SCV model was predicted using both axisymmetric and three-dimensional shell models. An axisymmetric continuum analysis of the top head and a three-dimensional shell analysis of the equipment hatch region were developed to provide detailed mappings of local model responses.
